The final pathway of CO₂ fixation is the **reductive acetyl-CoA pathway** (see Figure 14.34). This pathway is present in some obligately anaerobic species of *Bacteria* and *Archaea*, and because it is limited to anaerobes and found in both domains, it is thought to be of ancient origin. The reductive acetyl-CoA pathway is found in methanogens, many acetogens, and *Planctomyces* that carry out the anammox reaction (metabolisms to be described later in this chapter). The reductive acetyl-CoA pathway is the most efficient of all CO₂ fixation pathways and requires only about 1 ATP, 3 Fd_{red}, and 2 H₂ per 3 molecules of CO₂ fixed. It is also the only CO₂ fixation pathway coupled directly to energy conservation. The reductive acetyl-CoA pathway was likely one of the earliest mechanisms of

CO₂ fixation to appear on Earth and we will consider it in detail in Section 14.14.

We now pick up where we left off in Chapter 3 and explore the process of photosynthesis and the amazing diversity it supports.

Check Your Understanding

- What is the purpose of carboxysomes in cyanobacteria, and why are they not present in the chloroplasts of plants and algae?
- Make a hypothesis to explain why the rTCA cycle is present in diverse unrelated species of bacteria.
- What evidence supports the hypothesis that the reductive acetyl-CoA cycle was one of the first to appear on Earth?

II • Phototrophy

Phototrophs, which can be anoxygenic or oxygenic, use pigments to transfer light energy to photosynthetic reaction centers. Here they excite an electron to become a strong electron donor for photophosphorylation.

Phototrophy—the use of light energy—is widespread in the microbial world. Phototrophic organisms appeared early in the history of life, they are tremendously diverse, and they have transformed the biosphere. Ultimately, the origin of cyanobacteria billions of years ago converted Earth from an anoxic to an oxic world and set the stage for an explosion of eukaryotic microbial diversity that eventually gave rise to plants and animals (◀ Sections 1.5 and 13.2). In this section, we examine the properties and energy-conserving strategies of phototrophic microorganisms.

14.3 Photosynthesis and Chlorophylls

The most important biological process on Earth is **photosynthesis**, the use of light energy to drive biosynthesis. **Phototrophs** are

organisms that convert light energy into chemical energy. Photosynthetic organisms are phototrophs that are also **autotrophs**. Hence, photosynthetic organisms harness light energy to drive the reduction of CO₂ to organic compounds; this lifestyle is called *photoautotrophy*. It is important to note however that *not all phototrophs are autotrophic*. Some phototrophs use organic carbon as their carbon source; this lifestyle is called *photoheterotrophy*.

Phototrophy originated within the *Bacteria*, and a wide diversity of bacterial species can harvest energy from light. No less than seven different phototrophic systems have evolved within *Bacteria* and these systems are found in diverse phyla. These include the *Acidobacteria* (genus *Chloracidobacterium*), *Chlorobi* (green sulfur bacteria), *Chloroflexi* (green nonsulfur bacteria, also known as filamentous anoxygenic phototrophs), *Cyanobacteria*, *Firmicutes* (heliobacteria), *Gemmatimonadetes* (genus *Gemmatimonas*), and *Proteobacteria* (purple bacteria). Ultimately, phototrophy also evolved within the *Eukarya* as a result of the endosymbiotic origin of chloroplasts from cyanobacterial relatives (◀ Section 13.4). These phototrophic systems all differ in characteristic ways, but they all reveal similar underlying principles that we will review in the sections that follow.

Photosynthesis supporting autotrophic growth is comprised of two distinct sets of reactions that operate in parallel: the *light reactions* and the *light-independent reactions*. The term “light reactions” is used to describe those reactions that convert light energy into chemical energy in the form of the proton motive force and ATP. By contrast, the light-independent reactions are those of CO₂ fixation (Section 14.2). CO₂ fixation requires both ATP and reducing power (such as NAD(P)H or Fd_{red}); hence in addition to light, photosynthetic organisms need a source of electrons to fix CO₂ into cellular carbon.

Water (H₂O) is the electron donor for photosynthesis in cyanobacteria, algae, and green plants. When electrons are removed from H₂O, molecular oxygen (O₂) is produced as a waste product. Consequently, the term **oxygenic photosynthesis** describes phototrophic organisms that consume H₂O and produce O₂ as a waste product (Figure 14.5). However, phototrophic organisms can use many different electron donors other than H₂O and these organisms

Figure 14.5 Patterns of photosynthesis and examples of each. Energy and reducing power synthesis in (a) anoxygenic and (b) oxygenic phototrophs. Note that oxygenic phototrophs produce O₂, while anoxygenic phototrophs do not. Photos: Left, photomicrograph of cells of a typical anoxygenic phototroph, the purple sulfur bacterium *Chromatium*; cells are about 5 μm in diameter. Note the sulfur globules inside the cells produced from the oxidation of H₂S. Right, photomicrograph of cells of the cyanobacterium *Halothecae*; cells are about 5 μm in diameter.

do not produce O_2 as a waste product. For example, in green and purple sulfur bacteria the donor could be a reduced sulfur compound such as hydrogen sulfide (H_2S), or even molecular hydrogen (H_2). The term **anoxygenic photosynthesis** describes photosynthetic organisms that do not produce O_2 (Figure 14.5).

Photosynthesis requires light-sensitive pigments, the *chlorophylls*—present in plants, algae, and the cyanobacteria—and *bacteriochlorophylls*, present in anoxygenic phototrophs. Absorption of light energy by chlorophylls and bacteriochlorophylls begins the process of photosynthetic energy conversion, and the net result is chemical energy, ATP.

Chlorophyll and Bacteriochlorophyll

Chlorophyll and **bacteriochlorophyll** are tetrapyrroles that are related to the parent structure of the cytochromes. But unlike cytochromes, chlorophylls contain *magnesium* instead of *iron* at the center of the ring. Chlorophylls also contain specific substituents on the tetrapyrrole ring and a hydrophobic alcohol that helps anchor the chlorophyll into photosynthetic membranes. The structure of chlorophyll *a*, the principal chlorophyll of oxygenic phototrophs, is shown in Figure 14.6a. Chlorophyll *a* is green because it *absorbs* red and blue light and *transmits* green light; its absorption spectrum shows strong absorbance near 680 nm and 430 nm (Figure 14.6b). Several structurally distinct chlorophylls are known, each distinguished by its unique *absorption spectrum*. Cyanobacteria contain chlorophyll *a* (a few species contain chlorophyll *d* in place of *a*), while their relatives the prochlorophytes contain chlorophylls *a* and *b*.

Anoxygenic phototrophs produce one or more bacteriochlorophylls. Bacteriochlorophyll *a* (Figure 14.6 and Figure 14.7), present in most purple bacteria (► Sections 15.4 and 15.5), absorbs maximally between 800 and 925 nm. This range of wavelengths results from the fact that different species of purple bacteria synthesize photo-complexes of slightly different protein structure, and this affects the

absorption maxima of bacteriochlorophyll *a*. Other bacteriochlorophylls, whose distribution runs along phylogenetic lines, absorb in other regions of the visible and near-infrared spectrum (Figure 14.7). This diversity in photosynthetic pigments allows phototrophs, collectively, to absorb energy across a wide range of the electromagnetic spectrum. By employing different pigments with distinct absorption properties, different phototrophs can coexist in the same habitat, each absorbing wavelengths of light that others cannot. Thus, pigment diversity has *ecological* significance for the successful coexistence of different phototrophs in the same habitat.

Reaction Centers and Antenna Pigments

In oxygenic phototrophs and in purple anoxygenic phototrophs, chlorophyll/bacteriochlorophyll molecules do not exist freely in the cell but are attached to proteins and housed within membranes to form *photocomplexes* consisting of anywhere from 50 to 300 chlorophyll/bacteriochlorophyll molecules. A small number of these pigment molecules are present within photosynthetic **reaction centers** (Figure 14.8), the complex macromolecular structures that participate directly in the reactions that lead to energy conservation. Photosynthetic reaction centers are surrounded by larger numbers of light-harvesting chlorophylls/bacteriochlorophylls (shown as LH1 and LH2 in Figure 14.8). These so-called **antenna pigments** function to absorb light and funnel some of the energy to the reaction center (Figure 14.8). At the low light intensities that are often found in nature, this arrangement for concentrating energy allows reaction centers to receive light energy that would otherwise be missed.

Photosynthetic Membranes, Chloroplasts, and Chlorosomes

The chlorophyll pigments and all the other components of the light-gathering apparatus exist within membranes in the cell. The

Inset: Photomicrograph of cells of the green alga *Makinoella*. Each of the four cells in a cluster contains several chloroplasts.

location of these photosynthetic membranes differs between prokaryotic and eukaryotic phototrophs. In eukaryotic phototrophs, photosynthesis takes place in intracellular organelles, the **chloroplasts**, which contain sheetlike photosynthetic membrane systems called **thylakoids** (Figure 14.9); stacks of thylakoids within the chloroplast form **grana**. The thylakoids are arranged so that the chloroplast is divided into two regions, the matrix space that surrounds the thylakoids, called the **stroma**, and the inner space within the thylakoid array, called the **lumen**. This arrangement makes possible the generation of a light-driven proton motive force used to synthesize ATP (see Section 14.5).

Chloroplasts are absent from prokaryotic phototrophs. In purple bacteria, the photosynthetic pigments are integrated into internal membrane systems that arise from invagination of the cytoplasmic membrane. Membrane vesicles called **chromatophores** or membrane stacks called **lamellae** are common membrane arrangements in purple bacteria (Figure 14.10). In cyanobacteria, photosynthetic pigments reside in lamellar membranes (Figure 14.10b) that are also called **thylakoids** because of their resemblance to the thylakoids in the chloroplasts of algae (Figure 14.9).

The ultimate structure for capturing energy from low light intensities is the **chlorosome** (Figure 14.11). Chlorosomes are present in the green sulfur bacteria (*Chlorobium*, ► Section 15.6), green non-sulfur bacteria (*Chloroflexus*, ► Section 15.7), and phototrophic *Acidobacteria* (*Chloracidobacterium*, ► Section 15.8), all of which are anoxygenic phototrophs. Chlorosomes function as giant antenna systems, but unlike the antennae of purple bacteria or cyanobacteria, bacteriochlorophyll molecules in the chlorosome are not attached to proteins. Chlorosomes contain bacteriochlorophyll *c*, *d*, or *e* (Figure 14.7) arranged in dense arrays running along the long axis of the structure. Light energy absorbed by these antenna pigments is transferred to bacteriochlorophyll *a* in the reaction center in the cytoplasmic membrane through a small protein called the **FMO protein** (Figure 14.11).

Chlorosomes allow these phototrophs to grow at extremely low light intensities, and hence these phototrophs are typically found in the deepest waters of lakes, inland seas, and other anoxic aquatic habitats where light levels are too low to support other phototrophs. Green nonsulfur bacteria and *Chloracidobacterium* are major components of microbial mats, thick biofilms that form in

The chlorosome (green) lies appressed to the inside surface of the cytoplasmic membrane. Antenna bacteriochlorophyll (Bchl) molecules are arranged in tubelike arrays inside the chlorosome, and energy is transferred from these to reaction center (RC) Bchl *a* in the cytoplasmic membrane through a protein called FMO. Base plate (BP) proteins function as connectors between the chlorosome and the cytoplasmic membrane.

hot springs and highly saline environments (► Section 20.5). Microbial mats experience a steep light gradient, with light levels even a few millimeters into the mat approaching darkness. Green sulfur bacteria are common near the sediments of sulfidic aquatic systems and can even carry out photosynthesis in the darkness of the deep ocean by using infrared radiation emitted from hydrothermal vents. Hence, chlorosomes allow phototrophs that produce them to carry out photosynthesis with only the minimal light intensities available.

Check Your Understanding

- What is the fundamental difference between an oxygenic and an anoxygenic phototroph?
- What is the purpose of chlorophyll and bacteriochlorophyll molecules? In what ways do they resemble cytochromes and in what ways do they differ?
- Why can phototrophic green bacteria grow at light intensities that will not support purple bacteria or cyanobacteria?

14.4 Carotenoids and Phycobilins

Although chlorophyll/bacteriochlorophyll is required for photosynthesis, phototrophic organisms contain other pigments as well. These pigments include, in particular, the *carotenoids* and *phycobilins*.

Carotenoids

The most widespread accessory pigments in phototrophs are the **carotenoids**. Carotenoids are hydrophobic pigments that are firmly embedded in the photosynthetic membrane. **Figure 14.12** shows the structure of a common carotenoid, β -carotene. Carotenoids are typically yellow, red, brown, or green and absorb light in the blue region of the spectrum. Some of the major carotenoids of anoxygenic phototrophs are shown in **Figure 14.13**. Because they tend to mask the color of bacteriochlorophylls, carotenoids are responsible for the brilliant colors of red, purple, pink, green, yellow, or brown that are observed in different species of anoxygenic phototrophs (► Figure 15.12).

Carotenoids are closely associated with chlorophyll or bacteriochlorophyll in photosynthetic complexes, and some of the energy absorbed by carotenoids can be transferred to the reaction center. However, carotenoids function primarily as photoprotective agents. Bright light can be harmful to cells because it can catalyze photooxidation reactions that can produce toxic forms of oxygen, such as singlet oxygen ($^1\text{O}_2$). Like superoxide and other forms of toxic oxygen (◄ Section 4.16), singlet oxygen can spontaneously oxidize photocomplexes, rendering them nonfunctional. Carotenoids quench toxic oxygen species by absorbing much of this harmful light and in this way prevent these dangerous photooxidations. Because phototrophic organisms by their very nature must live in the light, the photoprotection conferred by carotenoids is clearly advantageous.

Phycobiliproteins and Phycobilisomes

Cyanobacteria and the chloroplasts of red algae (which are descendants of cyanobacteria, ► Section 18.1) contain pigments called **phycobiliproteins**, which are the main light-harvesting systems of these phototrophs. Phycobiliproteins consist of red or blue-green

Figure 14.12 Structure of β -carotene, a typical carotenoid. The conjugated double-bond system is highlighted in orange.

Figure 14.13 Structures of some common carotenoids found in anoxygenic phototrophs. Carotenes are hydrocarbon carotenoids, and xanthophylls are oxygenated carotenoids. Compare the structure of β -carotene shown in Figure 14.12 with how it is drawn here. For simplicity in the structures shown here, methyl (CH_3) groups are designated by bond only.

linear tetrapyrroles, called *bilins*, bound to proteins, and give cyanobacteria and red algae their characteristic colors (Figure 14.14). The red phycobiliprotein, called *phycoerythrin*, absorbs most strongly at wavelengths around 550 nm, whereas the blue phycobiliprotein, *phycocyanin* (Figure 14.14b), absorbs most strongly at 620 nm. A third phycobiliprotein, called *allophycocyanin* (Figure 14.14b) absorbs at about 650 nm.

Phycobiliproteins assemble into aggregates called **phycobilisomes** that attach to cyanobacterial thylakoids (Figure 14.14c). Phycobilisomes are arranged such that the allophycocyanin molecules are in direct contact with the photosynthetic membrane. Allophycocyanin is surrounded by phycocyanin or phycoerythrin (or both, depending on the organism). Phycocyanin and phycoerythrin absorb light of

shorter wavelengths (higher energy) and transfer some energy to allophycocyanin, which is positioned closest to the reaction center chlorophyll and transfers energy to it (Figure 14.14b). Thus, in a fashion similar to how antenna bacteriochlorophyll systems function in anoxygenic phototrophs (Figure 14.8), energy transfer proceeds “downhill” from phycobilisomes to the reaction center. Phycobilisomes thus facilitate energy transfer to cyanobacterial reaction centers, allowing cyanobacteria to grow at lower light intensities than would otherwise be possible.

- Phycocyanin is blue-green. What color of light does it absorb?

14.5 Anoxygenic Photosynthesis

In the photosynthetic light reactions, electrons travel through an electron transport chain whose components are arranged in a photosynthetic membrane in order of their increasingly more electro-positive reduction potential (E_0'), similar to the electron transport chains used in respiration (Sections 3.9–3.11). This electron transport generates a proton motive force that drives ATP synthesis (Section 3.11). Key parts of this process include photosynthetic reaction centers and photosynthetic membranes (Section 14.3).

Photosynthetic reaction centers are complex macromolecular structures localized within photosynthetic membranes. They are composed of multiple protein subunits and cofactors (including chlorophylls or bacteriochlorophylls), and they interact with both antenna pigments and components of the electron transport chain. Photosynthetic antenna pigments funnel light energy to the reaction center to excite a pair of chlorophylls or bacteriochlorophylls (referred to as the *special pair*), thereby generating highly electronegative electrons that can be donated to a subsequent electron transport chain. Several different types of reaction centers have been described in anoxygenic phototrophs, but all fall into one of two classes; they are either of a *quinone type* (Q-type) or *iron-sulfur type* (FeS-type) depending on the electron acceptor in the reaction center.

Photosynthetic Electron Flow in Purple Bacteria

Purple bacteria use a Q-type reaction center that contains three polypeptides, designated L, M, and H. These proteins along with a molecule of cytochrome *c* are firmly embedded in the photosynthetic membrane (Figure 14.10) and wind through the membrane several times (Figure 14.15). The L, M, and H polypeptides bind four molecules of bacteriochlorophyll *a*, two of which are the special pair and another two that transfer electrons within the reaction center, two molecules of bacteriopheophytin *a* (bacteriochlorophyll *a* minus its magnesium atom), two molecules of quinone (Section 3.8), and one carotenoid molecule (Figure 14.15).

Photosynthetic light reactions begin when light energy absorbed by antenna pigments is transferred to the special pair of bacteriochlorophyll *a* molecules (Figure 14.15a, Figure 3.25). This excites the special pair, converting them from a relatively weak to a very

Figure 14.14 Phycobiliproteins and phycobilisomes. (a) Light photomicrographs of cells of the cyanobacteria (top to bottom) *Dermocarpa*, *Anabaena*, and *Fischerella*, showing the typical blue-green color of cells due to phycobiliproteins. (b) Structure of phycocyanin (top) and a phycobilisome. Phycocyanin absorbs at higher energies (shorter wavelengths) than allophycocyanin. Chlorophyll *a* absorbs at longer wavelengths (lower energies) than allophycocyanin. Energy flow is thus phycocyanin → allophycocyanin → chlorophyll *a* of PSII (see Figure 14.16). (c) Electron micrograph of a thin section of the cyanobacterium *Synechocystis*. Note the darkly staining phycobilisomes (arrows) attached to the lamellar membranes.

strong electron donor (very electronegative E_0' , ◀ Sections 3.3 and 3.11). Once this strong donor has been produced, the remaining steps in photosynthetic electron flow are highly reminiscent of those we have seen before in respiration (◀ Sections 3.9 and 3.10); that is, electrons flow through a membrane from carriers of low E_0' to those of high E_0' and in the process generate a proton motive force that is used to synthesize ATP (◀ Section 3.11).

Before excitation, the purple bacterial reaction center, which is called *P870*, has an E_0' of about +0.5 V; after excitation, it has a

potential of about −1.0 V (Figure 14.16). An excited electron within *P870* proceeds to reduce a molecule of bacteriochlorophyll *a* within the reaction center (Figures 14.15 and 14.16). This transition takes place incredibly fast, taking only about three-trillionths (3×10^{-12}) of a second. Once reduced, bacteriochlorophyll *a* proceeds to reduce bacteriopheophytin *a*, and the latter reduces quinone molecules within the membrane (Figure 14.16). These transitions are also very fast, taking less than one-billionth of a second. From the quinone, electrons are transported through the membrane more slowly (on a

Figure 14.15 Structure of the reaction center of a purple phototrophic bacterium. (a) Arrangement of pigment molecules in the reaction center. The “special pair” of bacteriochlorophyll molecules (orange) overlap and occur at the top of the reaction center structural diagram; adjacent to and below the special pair are a pair of accessory

bacteriochlorophylls (yellow near the top). Bacteriopheophytin molecules (blue) are arranged below the bacteriochlorophylls, and quinones (yellow at the bottom) are present at the bottom of the structural model. Compare the structure of these molecules in the reaction center to their role in electron transfer (see Figure 14.16). (b) Molecular

model of the protein structure of the reaction center. The molecular structures (C in gray, O in red, N in blue) of pigments described in part a are depicted in context with ribbon diagrams of reaction center protein subunits: H (red), M (white), and L (blue). The reaction center pigment-protein complex is integrated into the lipid bilayer.

Figure 14.16 A comparison of electron flow in anoxygenic and oxygenic phototrophs. Purple bacteria and green sulfur bacteria have Q-type and FeS-type reaction centers (RC), respectively, while oxygenic phototrophs have both types. The FeS-type reaction center of green sulfur bacteria produces highly electronegative electrons that can reduce ferredoxin (Fd), allowing for CO₂ fixation through the reverse citric acid cycle (Figure 14.4). Q-type reaction centers cannot

reduce Fd, which makes reverse electron transport necessary to generate the NADH needed to fix CO₂ by the Calvin cycle (◀ Figures 3.26 and 3.27). Cyclic electron flow occurs in purple bacteria but not in green sulfur bacteria. Electron flow in oxygenic phototrophs is noncyclic, resulting in the characteristic “Z-scheme” pattern of electron flow. If photosystem II is blocked, oxygenic phototrophs can perform cyclic photosynthesis at photosystem I (dashed line in the cyanobacteria

panel, see also Figure 14.17). millisecond scale) through a series of iron–sulfur proteins and cytochromes used to generate the proton motive force (Figure 14.16), eventually returning to the reaction center. This overall process is referred to as *cyclic photophosphorylation* because the electrons cycle in a closed loop, thereby generating the proton motive force needed to synthesize ATP (◀ Section 3.11).

Overview of Electron Flow in Anoxygenic Phototrophs

Thus far, we have focused on electron flow in purple bacteria. Although analogous membrane-associated reactions drive photophosphorylation in other phototrophs, there are significant differences in the details. Q-type reaction centers that contain quinone molecules are found in purple bacteria (▶ Sections 15.4 and 15.5), green nonsulfur bacteria (▶ Section 15.7), and *Gemmatimonadetes* (genus *Gemmatimonas*, ▶ Section 15.8), but FeS-type reaction centers that lack quinones and contain instead FeS clusters are found in the green sulfur bacteria (▶ Section 15.6), *Acidobacteria* (genus *Chloracidobacterium*, ▶ Section 15.8), and heliobacteria (▶ Section 15.8). The Q-type and FeS-type reaction centers have important structural differences. For example, whereas Q-type reaction centers contain bacteriochlorophyll, FeS-type reaction centers contain both bacteriochlorophyll and chlorophyll *a* (green sulfur bacteria) or a modified form of chlorophyll *a* (hydroxychlorophyll *a* in heliobacteria). The structural differences between Q-type and FeS-type reaction centers cause major differences in electron flow (Figure 14.16).

The bacteriochlorophyll molecules of FeS-type reaction centers have an excited state that is significantly *more* electronegative than Q-type reaction centers (Figure 14.16). In purple bacteria, the Q-type reaction center donates electrons directly to a quinone (Figure 14.16). However, these quinones (E'_0 about 0 V) are insufficiently electronegative to provide the reducing power (E'_0 of -0.32 V for NAD(P)H and -0.42 V for ferredoxin) needed for CO₂ fixation and other biosynthetic reactions (Section 14.2). In contrast, FeS-type reaction centers donate electrons directly to low-potential FeS-proteins able to reduce ferredoxin. Green sulfur bacteria then use this Fd_{red} when they fix CO₂ using the rTCA cycle (Section 14.2 and Figure 14.4). Electrons from ferredoxin can also pass to ferredoxin–NAD⁺ oxidoreductase for the production of NAD(P)H needed for biosynthesis.

Phototrophs having a Q-type reaction center perform cyclic photophosphorylation providing cells with the ability to produce ATP as long as light is present, but these organisms still require a source of reducing power in order to perform the biosynthetic reactions required for growth. Since Q-type reaction centers produce electrons that are insufficiently electronegative to reduce NAD(P)⁺, these phototrophs require reverse electron transport (Section 14.1 and ◀ Section 3.11) to produce the NAD(P)H they need to carry out CO₂ fixation and other biosynthetic reactions.

It remains unclear whether electron transfer in green sulfur bacteria is cyclic or noncyclic. It has been proposed that the FeS-type reaction centers in these phototrophs can transfer electrons directly to menaquinone,

thereby generating a proton motive force resulting in cyclic photophosphorylation as seen in purple bacteria (Figure 14.16). However, little evidence for cyclic photophosphorylation has been observed in green sulfur bacteria. Alternatively, these phototrophs may employ noncyclic electron flow whereby electrons from external electron donors, such as H_2S , enter at the level of the menaquinone pool. These electrons would be transferred through the reaction center and then to ferredoxin where they would ultimately be channeled into biosynthetic reactions without the need for reverse electron transport (Figure 14.16). In heliobacteria, FeS-type phototrophs that are not autotrophic, cyclic photophosphorylation has also not been demonstrated. However, in this group of strictly photoheterotrophic bacteria, reducing power needs are less extensive than for photoautotrophs and thus it is more likely that cyclic flow occurs to generate sufficient ATP for biosynthesis.

We move on now to consider photosynthesis in oxygenic phototrophs such as the cyanobacteria. These organisms contain *both* FeS-type and Q-type reaction centers that likely evolved from those of green and purple bacteria, respectively. These two photocomplexes function in parallel to both generate ATP and reducing power, the latter from H_2O (Figure 14.16). We explore how this fascinating process occurs now.

Check Your Understanding

- What parallels exist in the processes of photophosphorylation and oxidative phosphorylation?
- Why is reverse electron transport needed by phototrophs having Q-type reaction centers and not needed by those having FeS-type reaction centers?
- What is the difference between cyclic and noncyclic photophosphorylation?

14.6 Oxygenic Photosynthesis

In contrast to photosynthetic electron flow in *anoxygenic* phototrophs, which have either FeS-type or Q-type photosynthetic reaction centers, *oxygenic* phototrophs have both types of reaction centers. In oxygenic phototrophs, electrons flow through two distinct photosystems called *photosystem I* (PSI, or P700), which has an FeS-type reaction center, and *photosystem II* (PSII, or P680), which has a Q-type reaction center. PSI and PSII interact in the “Z scheme” of photosynthesis, so named because the pathway resembles the letter Z turned on its side (Figure 14.16). As in anoxygenic photosynthesis, the light reactions in oxygenic photosynthesis occur in photocomplexes embedded in specialized photosynthetic membranes. In eukaryotic cells, the membranes are in the chloroplast (Figure 14.9), whereas in cyanobacteria, the membranes are arranged in stacks within the cytoplasm (Figure 14.14c).

Electron Flow and ATP Synthesis in Oxygenic Photosynthesis

PSII performs the first—and most distinctive—step in oxygenic photosynthesis, the splitting of water into oxygen and electrons (Figure 14.17). Upon absorbing light energy, the P680 chlorophyll *a* molecule in PSII is excited to a very electronegative reduction potential that allows it to donate an electron to pheophytin *a* (chlorophyll *a* lacking its magnesium atom), a molecule with an E_0' of about -0.5 V. This creates a charge separation that causes P680 to become so strongly electropositive that it can accept electrons from H_2O , an extremely weak electron donor. The oxidation of water by PSII occurs at the *water-oxidizing complex* and is catalyzed by a Mn_4Ca

Figure 14.17 Electron transport in oxygenic photosynthesis. Photosystem II (PSII) is activated by photons, causing H_2O to be oxidized on the Mn_4Ca cluster of the water-oxidizing complex. Electrons are transferred from PSII to the plastoquinone pool (PQ/PQH₂). Protons are exchanged across the membrane when plastoquinone is oxidized by cytochrome

b₆f. Per two molecules of water oxidized to one O₂, a total of 12 protons are released to the lumen to fuel ATP synthase. Electrons are then transferred to plastocyanin (PC), which carries them to photosystem I (PSI). Upon activation by light, PSI reduces ferredoxin (Fd), with sequential reduction of ferredoxin:NADP oxidoreductase (FNR), and then NADP⁺. The ATP and

NADPH produced by the light reactions are used in CO₂ fixation by the Calvin cycle (Section 3.12 and Section 14.2). Cyclic photophosphorylation occurs when FNR donates electrons to cytochrome *b₆f* instead of to NADP⁺. During cyclic photophosphorylation, more ATP and less NADPH are produced than during noncyclic photophosphorylation.

cluster (Figure 14.17), which binds 2 molecules of H_2O . P680 removes one electron from the Mn_4Ca cluster of the water-oxidizing complex for each photon absorbed. In this way 4 electrons are sequentially removed from the 2 H_2O molecules bound to the Mn_4Ca cluster, resulting in the production of O_2 and 4H^+ . Each electron transferred to pheophytin then travels through a series of quinones (Q_A and Q_B) within the PSII photocomplex. Finally, two electrons from the PSII photocomplex are used to reduce plastoquinone (PQ) to PQH_2 , a step that allows for the generation of the proton motive force.

The proton motive force is generated in oxygenic photosynthesis by electron transport through quinones and cytochromes of increasingly positive reduction potential. These electron transport reactions are similar to those encountered during our discussion of aerobic respiration (◀ Section 3.9). Electrons from PQH_2 are transferred through cytochrome b_6f and through a copper-containing protein called *plastocyanin* before being donated to the PSI reaction center (Figures 14.16 and 14.17). The absorption of light by P700 of PSI allows it to accept electrons donated from plastocyanin. Electrons travel through several intermediates in PSI terminating with the reduction of NADP^+ to NADPH (Figures 14.16 and 14.17). The electrons from NADPH are used in CO_2 fixation (by the Calvin cycle, ▶ Section 3.12 and Section 14.2) and other biosynthetic reactions, thereby regenerating NADP^+ and making CO_2 the ultimate electron acceptor for oxygenic photosynthesis. Two protons are generated for each water molecule that is split by PSII and four protons are translocated across the membrane for every two electrons transferred through the electron transport chain, resulting in a total of 12 protons translocated for every molecule of O_2 produced. This proton motive force is then used by ATP synthase to produce ATP.

Oxygenic photosynthesis results in *noncyclic photophosphorylation* because electrons do not cycle back to reduce the oxidized P680, but instead are used in the reduction of NADP^+ . However, when the cell requires less NADPH for biosynthesis, oxygenic phototrophs can perform *cyclic photophosphorylation*. This occurs when, instead of reducing NADP^+ , electrons from PSI are returned to the electron transport chain that connects PSII to PSI. When this happens, the recycled electrons can be used to generate a proton motive force that supports additional ATP synthesis (dashed line in the cyanobacteria panel of Figure 14.16; Figure 14.17).

Anoxygenic Photosynthesis in Oxygenic Phototrophs

Photosystems I and II normally function in tandem in oxygenic photosynthesis (Figures 14.16 and 14.17). However, if PSII activity is blocked, some oxygenic phototrophs can perform photosynthesis using only PSI. Under these conditions, cyclic photophosphorylation (Figure 14.16) occurs exclusively and reducing power for CO_2 reduction comes from sources other than water. In effect, this is anoxygenic photosynthesis occurring in oxygenic phototrophs.

Many cyanobacteria can use H_2S as an electron donor under these conditions, and many green algae can use H_2 . When H_2S is used, it is oxidized to elemental sulfur (S^0), and sulfur granules similar to those produced by green sulfur bacteria (Figure 14.5) are deposited outside the cyanobacterial cells. **Figure 14.18** shows this in the

Yehuda Cohen and Moshe Shilo

Figure 14.18 Oxidation of H_2S by *Oscillatoria limnetica*. Note the globules of S^0 (arrows), the oxidation product of H_2S , formed outside the cells. *O. limnetica* carries out oxygenic photosynthesis, but cells revert to the anoxygenic process in the presence of H_2S .

filamentous cyanobacterium *Oscillatoria limnetica*. This organism lives in anoxic salt ponds where it oxidizes sulfide and carries out anoxygenic photosynthesis along with green and purple bacteria.

From an evolutionary standpoint, the process of photophosphorylation in both oxygenic and anoxygenic phototrophs is one of many indications of their close relationship. Indeed, the structure of the Q-type reaction centers is homologous with PSII, and the structure of the FeS-type reaction centers is homologous with PSI. Because the evidence is strong that purple and green bacteria preceded cyanobacteria on Earth by perhaps as many as 0.5 billion years (▶ Section 13.2), it is clear that anoxygenic photosynthesis was the first form of photosynthesis on Earth. The key evolutionary event that ultimately led to the evolution of oxygenic photosynthesis in cyanobacteria was to acquire both types of reaction centers by horizontal gene transfer. The ancestors of cyanobacteria were certainly anoxygenic phototrophs, but the presence of redundant reaction centers facilitated their evolutionary diversification, as often results from gene duplication events (▶ Section 13.8). Ultimately, this process of functional diversification and experimentation led to the origin of oxygenic photosynthesis when chance events caused PSII to acquire the ability to use H_2O as an electron donor. The evolutionary origin of oxygenic photosynthesis was a seminal event in Earth's history since it not only oxygenated the planet (▶ Figure 13.1) but also allowed photoautotrophs to tap an inexhaustible supply of electrons.

In Part III we turn our attention to chemotrophic organisms that conserve energy through the respiration of inorganic electron donors.

Check Your Understanding

- Differentiate between cyclic and noncyclic electron flow in oxygenic photosynthesis.
- What is the key role of light energy in the initial step of the photosynthetic light reactions?
- What evidence is there that anoxygenic and oxygenic photosynthesis are related processes?

III • Respiratory Processes Defined by Electron Donor

Chemolithotrophs use inorganic electron donors such as H_2S , Fe^{2+} , or NH_3 in electron transport, generating ATP by oxidative phosphorylation. However, these electropositive donors force these organisms to generate NADH through endergonic reactions.

As we learned in Chapter 3 and reviewed in Section 14.1, energy is conserved in respiration by redox reactions that transfer electrons from an initial electron donor to a final electron acceptor. A tremendous diversity of respirations exist, and the microbes that carry them out are typically characterized by the nature of their electron donors and/or electron acceptors. In this part of the chapter, we focus on diversity from the standpoint of electron donors.

14.7 Oxidation of Sulfur Compounds

Many reduced sulfur compounds can be electron donors for the colorless sulfur bacteria, called *colorless* to distinguish them from the pigmented green and purple sulfur bacteria discussed earlier in this chapter (Figure 14.5 and Section 14.5). Historically, the concept of chemolithotrophy emerged in the late nineteenth century from studies of the sulfur bacteria by the Russian microbiologist Sergei Winogradsky (◀ Section 1.13) and was a radically new idea at the time. However, as our understanding of metabolic diversity has improved, it has become clear that chemolithotrophy, and in particular sulfur chemolithotrophy, is a major metabolic lifestyle of many *Bacteria* and *Archaea*.

Energetics of Sulfur Oxidation

The most common sulfur compounds used as electron donors are hydrogen sulfide (H_2S), elemental sulfur (S^0), thiosulfate ($\text{S}_2\text{O}_3^{2-}$), and sulfite (SO_3^{2-}) (Table 14.1, Table 14.2, and see Table 14.4). In most cases, the final oxidation product is sulfate (SO_4^{2-}). Sulfide oxidation occurs in stages, with the first oxidation step yielding elemental sulfur, S^0 . Some sulfide-oxidizing bacteria, such as *Beggiatoa*, deposit this elemental sulfur inside the cell (Figure 14.19a), where the sulfur exists as a potential energy (electron) reserve. When the supply of sulfide has been depleted, additional energy can then be conserved from the oxidation of sulfur to sulfate. When S^0 is present externally, the organism must attach itself to the sulfur particle because elemental sulfur is rather insoluble (Figure 14.19b).

One product of the oxidation of reduced sulfur compounds is protons (Tables 14.1 and 14.2). Consequently, one result of sulfur

(a)

(b)

Figure 14.19 Sulfur bacteria. (a) Internal sulfur granules in *Beggiatoa* (arrows). (b) Attachment of cells of the sulfur-oxidizing archaeon *Sulfolobus acidocaldarius* to a crystal of elemental sulfur. Cells were visualized by fluorescence microscopy after being stained with the dye acridine orange, which does not stain sulfur.

chemolithotrophy is acidification of the environment. Because of this, many sulfur bacteria have evolved to be acid-tolerant or even acidophilic. *Acidithiobacillus thiooxidans*, for example, grows best at a pH between 2 and 3.

Biochemistry of Sulfur Oxidation: The Sox System

There are diverse pathways for conserving energy from the oxidation of sulfur compounds. One of the best characterized is the Sox (for sulfur oxidation) system (Figure 14.20), which has been detailed in the bacterium *Paracoccus pantotrophus* and is widespread among sulfur-oxidizing bacteria. The Sox system contains over 15 genes encoding various cytochromes and other proteins necessary for the oxidation of reduced sulfur compounds directly to sulfate. Elements of the Sox system are found in diverse sulfur chemolithotrophs and also in some phototrophic sulfur bacteria, organisms that oxidize sulfide to obtain reducing power for CO_2 fixation rather than for energy conservation. The fact that this biochemical system is distributed among bacteria that oxidize sulfide for very different reasons is a good indication that the genes that encode Sox have been

TABLE 14.2 Comparison of the energetics of oxidation of some common reduced sulfur compounds

Chemolithotrophic reaction	Electrons	Stoichiometry ^a	Energetics (kJ/electron) ^a

^aAll reactions are balanced, both atomically and electrically. See Table 3.3 and Section 3.3 for details of calculations. For the reaction and energetics of the oxidation of sulfide to sulfur and sulfur to sulfate, see Table 14.1.

Sox/Dsr Systems

In the absence of Sox CD, some organisms will generate sulfur granules in the periplasm that are ultimately oxidized by reactions in the cytoplasm.

Figure 14.20 Oxidation of reduced sulfur compounds by sulfur chemolithotrophs. There are several different pathways for conserving energy through the oxidation of sulfide (H₂S), thiosulfate (S₂O₃²⁻), and elemental sulfur (S⁰). In the Sox system (sulfur oxidation), SoxXA attaches a reduced sulfur compound to the carrier protein SoxYZ. The protein SoxCD, sulfur dehydrogenase, catalyzes removal of 6 e⁻ from the bound sulfur atom, and is a key enzyme for bacteria that use the complete Sox system for sulfur oxidation (such as *Paracoccus pantotrophus*). Sulfate (SO₄²⁻) is released by the action of SoxB. In contrast, bacteria that form sulfur granules, such as *Beggiatoa* (Figure 14.19a), lack SoxCD and instead oxidize sulfur compounds using the enzymes DsrAB, dissimilatory sulfite reductase, and APS reductase (see Section 14.12). In sulfur oxidation, these enzymes are run backwards to oxidize sulfur compounds. In certain sulfur oxidizers, APS reductase is replaced by sulfite reductase. Reactions of the Sox cycle take place in the periplasm and electrons enter the electron transport chain through the activity of a periplasmic c-type cytochrome (Cyt c), while reactions of Sox/Dsr systems take place instead in the cytoplasm and electrons can enter electron transport at either the level of flavoproteins (Fp) or c-type cytochromes.

transferred between species by horizontal gene flow (◀ Section 13.9 and Chapter 9).

There are four key proteins in the Sox system: SoxXA, SoxYZ, SoxB, and SoxCD. All of these proteins are present in the periplasm (◀ Section 2.4). The pathway begins when the enzyme SoxXA forms a heterodisulfide bond between the sulfur compound to be oxidized (which can be HS⁻, S⁰, or S₂O₃²⁻) and the carrier protein, SoxYZ (Figure 14.20). The sulfur compound remains bound to the carrier throughout the pathway, being ultimately released as sulfate through the activity of SoxB. The enzyme SoxCD (sulfur dehydrogenase) is the key enzyme that mediates the removal of 6 electrons from the sulfur compound bound to the carrier (Figure 14.20). Electrons from the Sox system are funneled into the electron transport chain

(see later), while the protons generated in the periplasm are released to and acidify the external environment.

Other Aspects of Chemolithotrophic Sulfur Oxidation

Sulfur-oxidizing microbes that store sulfur granules within the cell (see Figure 14.19a) also use components of the Sox system but lack the key enzyme sulfur dehydrogenase (SoxCD). In the absence of SoxCD, a sulfur atom bound to SoxYZ is added to a growing sulfur granule in the periplasm (Figure 14.20). The sulfur in the granule can be reductively activated and transported to the cytoplasm where it is eventually oxidized to sulfite (SO₃²⁻) by the reverse activity of DsrAB, an enzyme homologous to the enzyme sulfite reductase found in sulfate-reducing bacteria (Section 14.12). The sulfite is then oxidized to sulfate plus two electrons through one of two different pathways. The most widespread system employs the reverse activity of the cytoplasmic enzyme *sulfite reductase*. This enzyme oxidizes sulfite and transfers the electrons to the electron transport chain. By contrast, some sulfur chemolithotrophs oxidize SO₃²⁻ to SO₄²⁻ via a reversal of the activity of the enzyme adenosine phosphosulfate (APS) reductase (an enzyme essential for the metabolism of sulfate-reducing bacteria, see Section 14.12). The

oxidation of SO₃²⁻ to SO₄²⁻ yields an energy-rich phosphate bond by substrate-level phosphorylation when AMP is converted to ATP (Figure 14.20).

Electrons from the oxidation of reduced sulfur compounds eventually reach the electron transport chain, as shown in Figure 14.20. Though the exact details remain unclear, electrons likely enter at the flavoprotein or cytochrome *c* (*E*₀' = +0.3 V) levels and are transported through the chain to O₂, generating a proton motive force that triggers ATP synthase activity (Figure 14.20). Electrons for CO₂ fixation come from reverse electron transport (Section 14.1), eventually yielding NADH, and autotrophy is driven by reactions of the Calvin cycle or some other autotrophic pathway (Section 14.2).

Although the sulfur chemolithotrophs are primarily an aerobic group, some species can grow by anaerobic respiration using nitrate as an electron acceptor. The sulfur bacterium *Thiobacillus denitrificans* is a classic example, reducing nitrate to dinitrogen gas (the process of denitrification, Section 14.11).

We now consider iron oxidation, a process that at acidic pH poses the greatest energy challenge of all chemolithotrophic energy metabolisms.

Check Your Understanding

- How many electrons are available from the oxidation of H_2S if S^0 or SO_4^{2-} is the final product?
- In terms of intermediates, how does the Sox system differ from other sulfide-oxidizing systems?
- Why are many sulfur- and sulfide-oxidizing bacteria acidophilic?

14.8 Iron (Fe^{2+}) Oxidation

The aerobic oxidation of ferrous iron (Fe^{2+}) to ferric iron (Fe^{3+}) supports growth of the chemolithotrophic “iron bacteria” (► Section 15.14 and see MicrobiologyNow on page 460). At acidic pH, only a small amount of energy is available from this reaction (Table 14.1), and for this reason the iron bacteria must oxidize large amounts of iron in order to produce only tiny amounts of cell material. The ferric iron produced becomes hydrated to form insoluble ferric hydroxide ($\text{Fe}^{3+} + 3 \text{H}_2\text{O} \rightarrow \text{Fe}(\text{OH})_3 + 3 \text{H}^+$) and other iron precipitates in aquatic environments (Figure 14.21), and this drives down the pH. This inevitable chemical reaction probably explains why many iron-oxidizing bacteria have evolved to be strongly acidophilic.

Iron-Oxidizing Bacteria

The best-known iron bacteria, *Acidithiobacillus ferrooxidans* and *Leptospirillum ferrooxidans*, can both grow autotrophically using ferrous iron (Figure 14.21) as electron donor at pH values as low as 1; growth is optimal at pH 2–3. These bacteria are common in acid-polluted environments such as coal-mining runoff waters (Figure 14.21a). *Ferroplasma*, a species of *Archaea*, is an extremely acidophilic iron oxidizer and can grow at pH values below 0 (► Section 17.3). We discuss the role of all of these organisms in acid mine pollution and mineral oxidation in ► Sections 21.6, 22.1, and 22.2.

At neutral pH, Fe^{2+} spontaneously oxidizes to Fe^{3+} , so opportunities for the iron bacteria in neutral habitats are restricted to locations where Fe^{2+} is transitioning from anoxic to oxic conditions. For example, anoxic groundwater often contains dissolved Fe^{2+} , and when it is released, as in iron-rich spring water, it becomes exposed to O_2 . At such interfaces, iron bacteria oxidize Fe^{2+} to Fe^{3+} before it oxidizes spontaneously. *Gallionella ferruginea*, *Sphaerotilus natans*, and *Leptothrix discophora* are examples of bacteria that live at these interfaces. They are typically seen mixed in with the characteristic ferric iron deposits they form (► Figures 15.55 and 21.6).

Energy from Iron Oxidation

The bioenergetics of ferrous iron oxidation by *Acidithiobacillus ferrooxidans* and other acidophilic iron oxidizers are of considerable interest because of the very electropositive reduction potential of the $\text{Fe}^{3+}/\text{Fe}^{2+}$ couple at acidic pH ($E_0' = +0.77 \text{ V}$ at pH 2). The

Figure 14.21 Iron-oxidizing bacteria. (a) Acid mine drainage, showing the confluence of a normal river and a creek draining a coal-mining area. At low pH values, Fe^{2+} does not oxidize spontaneously in air, but *Acidithiobacillus ferrooxidans* carries out the oxidation; insoluble $\text{Fe}(\text{OH})_3$ and complex ferric salts precipitate. (b) Cultures of *A. ferrooxidans*. Shown is a dilution series, with no growth in the tube on the left and increasing amounts of growth from left to right. Growth is evident from the production of $\text{Fe}(\text{OH})_3$.

respiratory chain of *A. ferrooxidans* contains cytochromes of the *c* and *aa*₃ types and a periplasmic copper-containing protein called *rusticyanin* (Figure 14.22). There is also an iron-oxidizing protein located in the outer membrane of this gram-negative bacterium.

Because the reduction potential of the $\text{Fe}^{3+}/\text{Fe}^{2+}$ couple is so high, steps in electron transport to oxygen ($\frac{1}{2} \text{O}_2/\text{H}_2\text{O}$, $E_0' = +0.82 \text{ V}$) are necessarily few. Iron oxidation begins in the outer membrane where the organism contacts either soluble Fe^{2+} or insoluble ferrous iron minerals such as FeS . Fe^{2+} is oxidized to Fe^{3+} , a one-electron transition (Table 14.1), by an outer membrane cytochrome *c* that transfers electrons into the periplasm where rusticyanin ($E_0' = +0.68 \text{ V}$) is the electron acceptor. This thermodynamically slightly unfavorable reaction is thought to be pulled forward by the immediate consumption of Fe^{3+} by $\text{Fe}(\text{OH})_3$ formation (Figure 14.22). Rusticyanin then reduces a periplasmic cytochrome *c* that transfers electrons to cytochrome *aa*₃, and it is the latter protein that reduces O_2 to H_2O ; ATP is synthesized by ATPase in the usual fashion (Figure 14.22).

The nature of the proton motive force in *A. ferrooxidans* is of interest. In a highly acidic environment, a large gradient of protons already exists across the *A. ferrooxidans* cytoplasmic membrane (the periplasm is pH 1–2, whereas the cytoplasm is about pH 6, Figure 14.22). Although one might think that with this gradient *A. ferrooxidans* could make ATP at no energetic cost, this is not the

Figure 14.22 Electron flow during Fe^{2+} oxidation by the acidophile *Acidithiobacillus ferrooxidans*. The periplasmic copper-containing protein rusticyanin receives electrons from Fe^{2+} oxidized by a *c*-type cytochrome located in the outer membrane. From here, electrons travel through a short electron transport chain, resulting in the reduction of O_2 to H_2O . Reducing power comes from reverse electron flow. Note the steep pH gradient across the cytoplasmic membrane.

case; the organism cannot make ATP from this preformed proton motive force in the absence of an electron donor. This is because H^+ ions that enter the cytoplasm via ATPase must be consumed in order to maintain the internal pH within acceptable limits. Proton consumption occurs during the reduction of O_2 in the electron transport chain and this reaction requires electrons; the latter come from the oxidation of Fe^{2+} to Fe^{3+} (Figure 14.22).

Autotrophy in *A. ferrooxidans* is supported by the Calvin cycle (Section 14.2), and because of the high potential of the electron donor, much energy must be consumed in reverse electron flow reactions to obtain the reducing power (NADH or NADPH) necessary to drive CO_2 fixation (Section 14.1). NADH is formed by reduction of NAD^+ by electrons obtained from Fe^{2+} that are forced backwards through cytochrome bc_1 and the quinone pool at the expense of the proton motive force (Figure 14.22).

The relatively poor energetic yield from ferrous iron oxidation coupled with the large energetic demands of the Calvin cycle means that *A. ferrooxidans* must oxidize large amounts of Fe^{2+} to produce even a very small amount of cell material. Thus, in environments where acidophilic iron-oxidizing bacteria thrive, their presence is signaled not by the formation of high cell numbers but by the presence of the extensive ferric iron precipitates they have generated (Figure 14.21). We consider the ecology of iron bacteria in Chapters 21 and 22.

Ferrous Iron Oxidation under Anoxic Conditions

Ferrous iron can be oxidized under *anoxic* conditions by certain chemolithotrophs and phototrophic purple and green bacteria

Figure 14.23 Fe^{2+} oxidation by anoxygenic phototrophic bacteria. (a) Oxidation in anoxic tube cultures. Left to right: Sterile medium, inoculated medium, a growing culture showing $\text{Fe}(\text{OH})_3$. (b) Phase-contrast photomicrograph of an Fe^{2+} -oxidizing purple bacterium, strain L7. The bright refractile areas within cells are gas vesicles (◀ Section 2.7). The granules outside the cells are iron precipitates. Strain L7 is phylogenetically related to the purple sulfur bacterium *Chromatium*.

(Figure 14.23). In these cases, Fe^{2+} is used either as an electron donor in energy metabolism (chemolithotrophs) and/or as a reductant for CO_2 fixation (phototrophs). An important point to consider here is that at neutral pH where these organisms thrive, the E_0' of the $\text{Fe}^{3+}/\text{Fe}^{2+}$ couple is significantly more electronegative than at acidic pH (+0.2 V versus +0.77 V, respectively, Figure 14.1). Hence, electrons from Fe^{2+} can reduce cytochrome *c* to initiate electron transport reactions. For chemolithotrophs, the electron acceptor is nitrate (NO_3^-) with either nitrite (NO_2^-) or dinitrogen gas (N_2) being the final product of this anaerobic respiration. For Fe^{2+} -oxidizing purple and green bacteria, either soluble Fe^{2+} or iron sulfide (FeS) can be used as electron donor. With FeS , both Fe^{2+} and S^{2-} are oxidized, Fe^{2+} to Fe^{3+} (one electron) and HS^- to SO_4^{2-} (eight electrons).

We now consider chemolithotrophic metabolisms of nitrogen compounds, major components of the nitrogen cycle in nature (▶ Section 21.3).

Check Your Understanding

- Why is only a very small amount of energy available from the oxidation of Fe^{2+} to Fe^{3+} at acidic pH?
- What is the function of rusticyanin and where is it found in the cell?
- How can Fe^{2+} be oxidized under anoxic conditions?

14.9 Nitrification

The reduced inorganic nitrogen compounds ammonia (NH_3) and nitrite (NO_2^-) are oxidized aerobically by the chemolithotrophic *nitrifying bacteria* in the process of **nitrification** (▶ Section 15.10). Nitrifying bacteria are widely distributed in soils, water, wastewaters, and the oceans. Nitrification consists of two different sets of

Figure 14.24 Oxidation of NH_3 and electron flow in the cytoplasmic membrane of ammonia-oxidizing bacteria. The reactants and the products of this reaction series are highlighted. The top surface of the membrane is the beginning of the periplasm. The cytochrome c (Cyt c) in the periplasm is a different form of Cyt c than that in the cytoplasmic membrane. AMO, ammonia monooxygenase; HAO, hydroxylamine oxidoreductase; Q, ubiquinone.

reactions; the first set of reactions catalyze oxidation of ammonia to nitrite, and the second set catalyze oxidation of nitrite to nitrate (NO_3^-). Most nitrifying microbes are only able to catalyze one set of these reactions. For example, *Bacteria* such as *Nitrosomonas* and *Archaea* such as *Nitrosopumilus* oxidize NH_3 only to NO_2^- , and we call these organisms *ammonia oxidizers*. The full nitrification pathway is ultimately completed when other *Bacteria* such as *Nitrobacter* oxidize NO_2^- to NO_3^- , and we call these organisms *nitrite oxidizers*. As far as is known, only certain bacteria in the genus *Nitrospira* can catalyze both sets of reactions, oxidizing NH_3 all the way to NO_3^- .

Bioenergetics and Enzymology of Ammonia and Nitrite Oxidation

Mastering Microbiology
Art Activity:
Figure 14.32
Oxidation of NH_3
and electron
flow in
ammonia-
oxidizing
bacteria

The bioenergetics of nitrification is based on the same principles that govern other chemolithotrophic reactions: Electrons from reduced inorganic substrates (in this case, reduced nitrogen compounds) enter an electron transport chain, and electron transport reactions establish a proton motive force that drives ATP synthesis. The complete oxidation of NH_3 to NO_3^- releases eight electrons, but the electron donors for the nitrifying bacteria are not particularly strong. For example, the E_0' of the $\text{NO}_2^-/\text{NH}_3$ couple (the first step in the oxidation of NH_3) is $+0.34\text{ V}$, and the E_0' of the $\text{NO}_3^-/\text{NO}_2^-$ couple is even more positive, about $+0.43\text{ V}$. By necessity, these reduction potentials force the nitrifying bacteria to donate electrons to rather high-potential electron acceptors, and this of course limits the amount of energy that can be conserved (Section 14.1).

Mastering Microbiology
Art Activity:
Figure 14.33
Oxidation of
 NO_2^- to NO_3^-
by nitrifying
bacteria

Several key enzymes participate in the oxidation of reduced nitrogen compounds. In ammonia-oxidizing bacteria such as *Nitrosomonas*, NH_3 is oxidized by *ammonia monooxygenase* (AMO; monooxygenases

are discussed in Section 14.23), producing hydroxylamine (NH_2OH) and H_2O (Figure 14.24). A second key enzyme, *hydroxylamine oxidoreductase* (HAO), then oxidizes NH_2OH to NO_2^- , removing four electrons in the process. AMO is an integral membrane protein, whereas HAO is periplasmic (Figure 14.24). In the reaction carried out by AMO,

two electrons and two protons are needed to reduce one molecule of oxygen (O_2) to H_2O . These electrons originate from the oxidation of hydroxylamine and are supplied to AMO from HAO (Figure 14.24). Thus, for every four electrons generated from the oxidation of NH_3 to NO_2^- , only two actually reach the terminal oxidase that interacts with O_2 to form H_2O (Figure 14.24).

Nitrite-oxidizing bacteria such as *Nitrobacter* oxidize NO_2^- to NO_3^- by the enzyme *nitrite oxidoreductase*, with electrons traveling a very short electron transport chain (because of the high potential of the $\text{NO}_3^-/\text{NO}_2^-$ couple) to the terminal oxidase (Figure 14.25). Cytochromes of the c and bd types are present in the electron transport chain of nitrite oxidizers, and the activity of the bd -type cytochrome generates a proton motive force (Figure 14.25). As is the case with the iron bacteria (Section 14.8), only small amounts of energy are available from nitrite oxidation. Hence, minimal amounts of cell material are obtained even though large amounts of nitrite may be oxidized.

Carbon Metabolism and Ecology of Nitrifying Bacteria

Like sulfur- and iron-oxidizing chemolithotrophs (Sections 14.7 and 14.8), aerobic nitrifying *Bacteria* employ the Calvin cycle for CO_2 fixation. The ATP and reducing power requirements of the Calvin cycle place additional burdens on an energy-generating system that already has a relatively low yield; NAD(P)H to drive the Calvin cycle in nitrifiers is formed by reverse electron flow (Figures 14.24

Figure 14.25 Oxidation of NO_2^- to NO_3^- by nitrifying bacteria. The reactants and products of this reaction series are highlighted to show the reaction clearly. NXR, nitrite oxidoreductase; Cyt, cytochrome.

and 14.25). The energetic constraints are particularly severe for nitrite oxidizers, and it is perhaps for this reason that most of these organisms have alternative energy-conserving mechanisms, being able to grow chemoorganotrophically on glucose and a few other organic substrates. By contrast, species of ammonia-oxidizing bacteria are either obligate chemolithotrophs and autotrophs, or are mixotrophic, both fixing CO₂ and using organic compounds (Section 14.2). Autotrophy in ammonia-oxidizing *Archaea* is supported by the 3-hydroxypropionate/4-hydroxybutyrate cycle (Section 14.2).

Nitrifying microbes play key ecological roles in the nitrogen cycle, converting ammonia in soils into nitrate, a key plant nutrient. Nitrifiers are also important in sewage and wastewater treatment, removing toxic amines and ammonia and releasing less toxic nitrogen compounds (► Sections 22.6 and 22.7). Nitrifiers play a similar role in the water column of lakes, where ammonia produced in the sediments from the decomposition of organic nitrogenous compounds is oxidized to nitrate, a more usable fixed nitrogen source for algae and cyanobacteria.

Although classical nitrifiers are obligate aerobes, we will see next that ammonia can be oxidized anaerobically as well, by a unique group of *Bacteria*.

Check Your Understanding

- What are the substrates for the enzyme ammonia monooxygenase?
- What is the difference between ammonia oxidation and nitrite oxidation, and in what types of organisms are these reactions found?
- Why do both ammonia- and nitrite-oxidizing bacteria require reverse electron transport?

14.10 Anaerobic Ammonia Oxidation (Anammox)

In addition to the oxygen-dependent process of ammonia oxidation by organisms such as *Nitrosomonas* and *Nitrosopumilus*, NH₃ can also be oxidized under anoxic conditions. This process is called **anammox** (for *anaerobic ammonia oxidation*) and is catalyzed by an unusual group of obligately anaerobic *Bacteria*.

Ammonia is oxidized in the anammox reaction using NO₂[−] as the electron acceptor to yield N₂:

A major anammox organism, *Brocadia anammoxidans*, is a species of the *Planctomycetes* phylum of *Bacteria* (► Section 16.16). *Planctomycetes* are structurally unusual *Bacteria* because their cytoplasm can contain membrane-enclosed compartments of various types (Figure 14.26). In cells of *B. anammoxidans*, this compartment is the *anammoxosome*, and it is within this structure that the anammox reaction occurs (Figure 14.26c). In addition to *Brocadia*, several other genera of anammox bacteria are known, including *Kuenenia*, *Anammoxoglobus*, *Jettenia*, and *Scalindua*, all of which are related to *Brocadia* and also contain anammoxosomes. Like aerobic ammonia oxidizers, anammox bacteria are also autotrophs, but they do not fix CO₂ using the pathways employed by aerobic ammonia oxidizers. Instead, anammox bacteria fix CO₂ by way of the reductive

Figure 14.26 Anammox. (a) Phase-contrast photomicrograph of cells of *Brocadia anammoxidans*. A single cell is about 1 μm in diameter. (b) Transmission electron micrograph of a *Brocadia* cell; note the membrane-enclosed compartments including the large fibrillar anammoxosome. (c) Reactions in the anammoxosome. acetyl-CoA pathway, an autotrophic pathway widespread among some obligately anaerobic autotrophic *Bacteria* and *Archaea* (see Section 14.14).

The Anammoxosome and Its Reactions

The anammoxosome is a unit membrane-enclosed structure (Figure 14.26b) and in this respect is technically an organelle in the eukaryotic sense of the term. Lipids that form the anammoxosome membrane are not the typical lipids of *Bacteria* but instead consist of fatty acids constructed of multiple cyclobutane (C₄) rings bonded to glycerol by both ester and ether bonds. These *ladderane lipids*, as they are called, aggregate in the membrane to form an unusually dense membrane structure that prevents diffusion of substances from the anammoxosome into the cytoplasm.

The sturdy anammoxosome membrane is required to protect the cell from toxic intermediates produced during anammox reactions. These include, in particular, the compound *hydrazine* (N₂H₄), a very strong reductant. In the anammox reaction, NO₂[−] is first reduced to nitric oxide (NO) by nitrite reductase, and then NO reacts with ammonium (NH₄⁺) to yield N₂H₄ by activity of the enzyme hydrazine synthase (Figure 14.26c). (Note that while NH₃ is the substrate

for AMO in aerobic ammonia-oxidizing bacteria [Figure 14.24], NH_4^+ is the substrate for hydrazine synthase in the anaerobic anammox bacteria.) N_2H_4 is then oxidized to N_2 plus electrons by the enzyme hydrazine dehydrogenase, and the electrons are funneled into the electron transport chain where they are used to reduce NO_2^- and NO earlier in the pathway. In this way, anammox generates a *cyclical* series of electron transfer reactions in order to generate a proton motive force; ATP is formed from the latter by ATPases in the anammoxosome membrane (Figure 14.26c).

Reducing power for CO_2 fixation by anammox bacteria is derived from reverse electron transport (Section 14.1), but because electron transfer reactions are cyclic, the electrons needed for reverse electron transport derive from an independent set of reactions that oxidize NO_2^- to NO_3^- by a nitrite oxidoreductase, a reaction also present in *Nitrobacter* (Figure 14.25). Interestingly, then, NO_2^- serves two different purposes for anammox bacteria: The *reduction* of nitrite is required to generate ATP by chemiosmosis, whereas the *oxidation* of nitrite is required to generate reducing power for CO_2 fixation.

Ecology of Anammox

In nature, the source of NO_2^- for the anammox reaction is presumably aerobic ammonia-oxidizing *Bacteria* and *Archaea*. These organisms coexist with anammox bacteria in ammonia-rich habitats such as sewage and other wastewaters. The suspended particles that form in these habitats contain both oxic and anoxic zones in which ammonia oxidizers of different physiologies can coexist in close association. In mixed laboratory cultures, high levels of oxygen inhibit anammox and favor classic nitrification, and thus it is likely that in nature, the fraction of ammonia oxidation catalyzed by anammox bacteria is governed by the concentration of O_2 in the habitat.

From an environmental standpoint, anammox is a very beneficial process in the treatment of wastewaters. The anoxic removal of ammonia and amines by the formation of N_2 (Figure 14.26c) helps reduce the input of fixed nitrogen from wastewater treatment effluents that flow into rivers and streams, thereby maintaining higher water quality than would otherwise be possible. Also, marine anammox bacteria are likely responsible for the large amount of NH_3 that is known to disappear during mineralization processes in anoxic marine sediments. At least some ammonia-rich freshwater lake sediments also support anammox, and thus it appears that anammox can occur in any anoxic environment in which NH_3 and NO_2^- coexist.

We move on to Part IV now where chemotrophic energy metabolisms will be defined not by the electron *donor* that is used, but by the electron *acceptor* that is used to receive electrons from a wide variety of donors.

Check Your Understanding

- Name the electron donor and the electron acceptor in the anammox process.
- What does electron transport for reducing power synthesis in chemolithotrophs (e.g., anammox bacteria, nitrifiers, and sulfide oxidizers) have in common with that of purple sulfur bacteria?
- Compare autotrophy in anammox bacteria and purple sulfur bacteria. What characteristics do these processes share and how are they different?

IV • Respiratory Processes Defined by Electron Acceptor

Anaerobic respiration occurs when an alternative electron acceptor is substituted for oxygen in respiration. Many forms of anaerobic respiration are possible using oxidized nitrogen and sulfur compounds, and some metals and organic compounds support the process as well.

We examined the process of aerobic respiration in Chapter 3 and reviewed the bioenergetics of respiration in Section 14.1. Here we consider the details of **anaerobic respiration** in its many variations found in the microbial world. Diverse compounds function as electron acceptors in anaerobic respirations (Figure 14.1), and each acceptor has its own redox properties and is typically linked to a specific group or groups of microbes. We begin with a common form of anaerobic respiration in which nitrate functions as electron acceptor.

14.11 Nitrate Reduction and Denitrification

Inorganic nitrogen compounds are some of the most common electron acceptors in anaerobic respiration. **Table 14.3** summarizes the relevant forms of inorganic nitrogen with their oxidation states. One of the most common alternative electron acceptors for dissimilative purposes is nitrate (NO_3^-), which can be reduced with two electrons to nitrite (NO_2^-), or reduced further to nitric oxide (NO), nitrous oxide (N_2O), or dinitrogen (N_2). Because NO , N_2O , and N_2 are all gases, they can be lost from the environment, and their biological production is called **denitrification** (Figure 14.27).

Some nitrate reducers, for example *Escherichia coli*, are not true denitrifiers, but only carry out the first step (NO_2^- to NO_3^-) in the process (Figure 14.27 and ◀ Figure 3.23). Moreover, some organisms can reduce NO_2^- to ammonia (NH_3) in a dissimilative process. But it is the production of gaseous products—*denitrification*—that is of greatest global significance because it consumes fixed nitrogen and produces some polluting gases.

Denitrifying Microorganisms and Their Ecological Activities

Many denitrifying *Bacteria* are phylogenetically *Proteobacteria* and physiologically facultative aerobes. *Pseudomonas* species, for example, are typically strong denitrifiers. Aerobic respiration occurs when O_2 is present, even if NO_3^- is also present in the medium. Many denitrifying bacteria also reduce other electron acceptors anaerobically, such

TABLE 14.3 Oxidation states of key nitrogen compounds

Compound	Oxidation state of N atom
Organic N ($-\text{NH}_2$)	-3
Ammonia (NH_3)	-3
Nitrogen gas (N_2)	0
Nitrous oxide (N_2O)	+1 (average per N)
Nitric oxide (NO)	+2

Nitrogen dioxide (NO_2)	+4
Nitrate (NO_3^-)	+5

Figure 14.27 Steps in the dissimilative reduction of nitrate. Some organisms can carry out only the first step. All enzymes involved are derepressed by anoxic conditions. Also, some bacteria are known that can reduce NO_3^- to NH_4^+ in dissimilative metabolism. Note that colors used here match those used in Figure 14.28.

as Fe^{3+} and certain organic electron acceptors (Figure 14.1), and some denitrifiers can even ferment. Thus, denitrifying bacteria are metabolically diverse in terms of alternative energy-generating mechanisms. Some species of *Archaea* can grow anaerobically by nitrate reduction to nitrite, and several others can denitrify. Interestingly, at least one eukaryote has also been shown to be a denitrifier. The protist *Globobulimina pseudospinescens*, a shelled amoeba (a foraminiferan, ► Section 18.6), can denitrify and likely employs this form of metabolism in its habitat, anoxic marine sediments.

Denitrification is a process with significant ecological ramifications. For agricultural purposes, denitrification is a detrimental process, as it removes nitrate—often intentionally added by grain and other crop farmers as potassium nitrate fertilizer—from the soil. Gaseous products of denitrification other than N_2 (N_2O and NO) are also of significant environmental concern. N_2O is a strong greenhouse gas (contributing to climate change) and can also be converted to NO by sunlight; NO reacts with and consumes ozone (O_3) in the upper atmosphere to form NO_2^- . When it rains, NO_2^- returns to Earth as nitrous acid (HNO_2) in *acid rain*. In contrast to these environmentally harmful processes, for a desirable process such as

sewage treatment, denitrification (as well as anammox, see earlier) is beneficial. This is because denitrification removes fixed nitrogen, a major trigger of algal growth if a nitrate-rich sewage effluent is released into rivers or lakes (► Sections 22.6 and 22.7).

Biochemistry of Dissimilative Nitrate Reduction

The electron transport pathway of denitrification is shown in Figure 14.28. The enzyme that catalyzes the first step of dissimilative nitrate reduction is *nitrate reductase*, a molybdenum-containing, membrane-integrated enzyme whose synthesis is repressed by O_2 . All subsequent enzymes of the pathway are coordinately regulated and thus also repressed by O_2 . In addition to anoxic conditions, nitrate must also be present before these enzymes are fully expressed.

The biochemistry of dissimilative nitrate reduction has been studied in detail in *E. coli*, in which NO_3^- is reduced only to NO_2^- (◄ Section 3.10) and *Paracoccus denitrificans* and *Pseudomonas stutzeri*, in which denitrification occurs. In *P. denitrificans* and *P. stutzeri*, nitrogen oxides are formed enzymatically from NO_2^- by nitrite reductase, nitric oxide reductase, and nitrous oxide reductase (Figure 14.28). NO and N_2O are gaseous intermediates that are free to escape from the cell, and N_2O in particular is a major product of denitrification, though these intermediates are often reduced all the way to N_2 . During these electron transport reactions, a proton motive force is established (Figure 14.28), and ATPase couples this to the synthesis of ATP.

We move on from coverage of nitrogen compounds as electron acceptors in anaerobic respiration to consider sulfur compounds as electron acceptors in the next section. A diverse group of organisms will be in play here that generate a potentially toxic product but one that is central to the sulfur cycle. Following that, we round out this part of the chapter by considering a few key metals and organic compounds as electron acceptors.

Check Your Understanding

- Under what condition would you expect the genes for denitrification to be repressed?
- If the final product of denitrification is N_2 then why is N_2O released into the environment?
- Where is dissimilative nitrate reductase found in the cell? What unusual metal does it contain?

14.12 Sulfate and Sulfur Reduction

Several inorganic sulfur compounds are important electron acceptors in anaerobic respiration, and Table 14.4 lists the oxidation states of the key compounds. Sulfate (SO_4^{2-}), the most oxidized form of sulfur, is reduced by the *sulfate-reducing bacteria*, a highly diverse group of obligately anaerobic bacteria widely distributed in nature. The product of sulfate reduction is hydrogen sulfide, H_2S (which occurs mostly as HS^- at pH 7), an important and potentially toxic natural product that participates in many biogeochemical processes (► Sections 21.4, 22.6, and 22.7). Sulfate-reducing species in the genus *Desulfovibrio*, in particular *D. desulfuricans*, have been widely studied, and the general properties of sulfate-reducing bacteria are discussed in Section 15.11.

As was the case with nitrate metabolism (Section 14.11), it is necessary to distinguish between assimilative and dissimilative sulfate metabolism. Most microbes can incorporate sulfate for biosynthetic purposes to make cysteine, methionine, and many other organosulfur compounds; this is *assimilative* sulfate metabolism. By contrast, the ability to use sulfate as an electron acceptor for energy conservation requires its large-scale reduction and is restricted to the sulfate-reducing bacteria. H_2S is produced on a very large scale by these organisms and is excreted from the cell, free to be oxidized by air, used by other organisms, or combined with metals to form metal sulfides. Although a major electron donor to many microbes, an environmental concern of H_2S production is the fact that sulfide is highly toxic to higher organisms such as fish and wildlife. When anoxic conditions develop in sulfate-containing waters, the production of H_2S can cause die-offs of fish and other aquatic organisms and reduce water quality for recreational use or consumption.

Biochemistry and Energetics of Sulfate Reduction

As shown in Figure 14.1, SO_4^{2-} is an energetically much less favorable electron acceptor than is O_2 or NO_3^- . Hydrogen (H_2) is used as an electron donor by virtually all species of sulfate reducers, whereas the use of organic electron donors is more restricted. For example, lactate and pyruvate are widely used by sulfate-reducing bacteria found in freshwater anoxic environments while acetate and longer-chain fatty acids are widely used by marine sulfate-reducing bacteria. Many morphological and physiological types of sulfate-reducing bacteria are known, and with the exception of *Archaeoglobus* (► Section 17.4), a genus of *Archaea*, all known sulfate reducers are *Bacteria* (► Section 15.11).

TABLE 14.4 Sulfur compounds for sulfate reduction

Compound	Oxidation state of S atom
Organic S ($\text{R}-\text{SH}$)	-2
Sulfide (H_2S)	-2
Elemental sulfur (S^0)	0
Thiosulfate ($-\text{S}-\text{SO}_3^{2-}$)	-2/ + 6
Sulfur dioxide (SO_2)	+4
Sulfite (SO_3^{2-})	+4
Sulfate (SO_4^{2-})	+6

The reduction of SO_4^{2-} to H_2S requires eight electrons and proceeds through a number of intermediate stages. The reduction of SO_4^{2-} requires that it first be *activated* in a reaction requiring ATP. The enzyme ATP sulfurylase catalyzes the attachment of SO_4^{2-} to a phosphate of ATP, forming *adenosine phosphosulfate* (APS) as shown in Figure 14.29a. Activation raises the extremely electronegative E_0' of the $\text{SO}_4^{2-}/\text{SO}_3^{2-}$ couple (-0.52 V) to near 0 V , making reduction of the sulfate moiety possible with electron donors such as NADH (-0.32 V). In *dissimilative* sulfate reduction, the SO_4^{2-} in APS is reduced directly to sulfite (SO_3^{2-}) by the enzyme APS reductase with the release of AMP. In *assimilative* reduction, by contrast, a

(a)

(b)

Figure 14.29 Biochemistry of sulfate reduction: Activated sulfate. (a) Two forms of active sulfate can be made, adenosine 5'-phosphosulfate (APS) and phosphoadenosine 5'-phosphosulfate (PAPS). Both are derivatives of adenosine diphosphate (ADP), with the second phosphate of ADP being replaced by SO_4^{2-} . (b) Schemes of assimilative and dissimilative sulfate reduction.

second phosphate is added to APS to form *phosphoadenosine phosphosulfate* (PAPS) (Figure 14.29a), and only then is the SO_4^{2-} reduced. However, in both cases the product of sulfate reduction is sulfite (SO_3^{2-}), and once SO_3^{2-} is formed, it is reduced to H_2S by a sulfite reductase enzyme (Figure 14.29b).

Sulfate reduction offers only a very low free-energy yield and so organisms have developed a variety of mechanisms to optimize electron flow and energy conservation. During dissimilative sulfate reduction, electron transport reactions generate a proton motive force and this drives ATP synthesis by ATPase. *Cytochrome c_3* , a periplasmic low-potential cytochrome (Figure 14.30), is a major intermediate in these reactions. *Cytochrome c_3* can accept electrons from several different periplasmic hydrogenase enzymes and can transfer these electrons to a number of different membrane-associated protein complexes. **Hydrogenases** are enzymes that perform redox reactions that produce or consume H_2 . Sulfate reducers that use organic substrates typically do so by oxidizing these substrates to produce H_2

that then feeds into the electron transport chain by way of these periplasmic hydrogenases and cytochrome c_3 (Figure 14.30).

Dissimilative sulfate reduction requires several enzymes that perform *flavin-based electron bifurcation* (Section 14.1). For example, the reduction of APS to SO_3^{2-} requires the activity of the APS reductase complex (Figure 14.30). The APS reductase complex includes membrane-bound proteins that funnel electrons from a reduced quinone to a cytoplasmic enzyme that performs an electron confurcation reaction (Section 14.1) combining $2e^-$ from reduced ferredoxin (Fd_{red}) and $2e^-$ from the quinone to reduce 2 APS to 2 SO_3^{2-} . In addition, the dissimilative reduction of SO_3^{2-} to HS^- occurs in two steps. The first step is a two-electron transfer mediated by dissimilatory sulfite reductase (DsrAB); this reaction forms a heterodisulfide bond between S (from SO_3^{2-}) and the protein DsrC (Figure 14.30). The heterodisulfide is reduced in a four-electron transfer mediated by an electron-bifurcating heterodisulfide reductase (Hdr, reaction 4 in Figure 14.30). This Hdr reaction is similar to a key reaction in methanogenesis (see

Figure 14.30 Electron transport and energy conservation in sulfate-reducing bacteria. H_2 serves as primary electron donor for sulfate reduction, and growth on organic compounds such as lactate result in the production of H_2 as an intermediate. The periplasmic cytochrome c_3 transfers electrons from a system of periplasmic hydrogenases (H_2ase) to membrane-bound proteins that mediate electron

transfer reactions. Core components of electron transfer are shown in purple, and also shown are components required for growth exclusively on H_2 (in green) and on lactate (in blue). The scheme is proposed to include three bifurcating enzymes. Electron bifurcation at the APS reductase complex results in the donation of electrons to APS. Electron bifurcation at the heterodisulfide reductase complex (Hdr) results

in the donation of electrons to Dsr-C and the release of HS^- . An electron confurcation at the CO-induced hydrogenase complex (Coo) contributes to redox balance during growth on lactate. Energy-converting hydrogenases (see Section 14.17) contribute to energy conservation in addition to quinone cycling.

Section 14.15 and Figure 14.38). These cells also balance electron flow using an **energy-converting hydrogenase**, a membrane-bound hydrogenase enzyme that uses the exergonic reduction of protons by Fd_{red} to generate a pmf (Figure 14.30). This reaction has a standard free-energy change ($\Delta G^{\circ'}$) close to zero, but under natural conditions, the ΔG is typically exergonic. A net of about two ATP is produced for each SO_4^{2-} reduced to HS^- by H_2 , and the reaction is

Oxidation of organic compounds, such as lactate, is used to produce H_2 through energy-converting hydrogenases or by electron confurcation (Figure 14.30). This H_2 crosses the cytoplasmic membrane and is oxidized by the periplasmic hydrogenase to electrons—which are fed back into the system—and protons, which establish the proton motive force (Figure 14.30). When lactate or pyruvate is the electron donor, ATP is produced not only from pmf but also by substrate-level phosphorylation during the oxidation of pyruvate to acetate plus CO_2 (reaction 9 in Figure 14.30). Many strains are ultimately unable to further oxidize acetate and so while some acetate is assimilated during biosynthetic reactions, the remainder is excreted from the cell.

Marine but not freshwater species of sulfate-reducing bacteria can couple sulfate reduction and the oxidation of acetate (and longer-chain fatty acids) to CO_2 :

The mechanism for acetate oxidation in most of these species is the *reductive acetyl-CoA pathway*, a series of reversible reactions used by many anaerobes for acetate synthesis or acetate oxidation (Section 14.14). A few sulfate-reducing bacteria can also grow autotrophically with H_2 . Under these conditions, the organisms use the reductive acetyl-CoA pathway for making acetate as a carbon source. Such species can be cultured in a completely organic-free medium containing only mineral salts, sulfate, CO_2 , and H_2 .

Special Metabolisms of Sulfate-Reducing Bacteria

Certain species of sulfate-reducing bacteria can catalyze reactions not characteristic of all species. These include *sulfur reduction*, *disproportionation*, and even *phosphite oxidation*. Most sulfate-reducing bacteria can also conserve energy from the reduction of elemental sulfur to sulfide ($\text{S}^0 + 2 \text{H} \rightarrow \text{H}_2\text{S}$). The electrons for sulfur reduction come from H_2 or any of a number of organic compounds. For example, *Desulfuromonas acetoxidans* can oxidize acetate or ethanol to CO_2 coupled to the reduction of S^0 to H_2S .

Many microbes can reduce elemental sulfur but not sulfate in anaerobic respiration. These are the *sulfur reducers*, a diverse group of *Bacteria* and *Archaea* that often coexist with sulfate-reducing bacteria in anoxic, sulfur-rich habitats. Sulfur reducers lack the capacity to activate sulfate to APS (Figure 14.29), and presumably this is what excludes them from using SO_4^{2-} as an electron acceptor.

Disproportionation is a process in which one molecule of a substance is oxidized while a second molecule is reduced, ultimately forming two different products. For example, *Desulfovibrio sulfodismutans* can disproportionate thiosulfate ($\text{S}—\text{SO}_3^{2-}$) as follows:

Note that in this reaction, the right-hand sulfur atom of $\text{S}—\text{SO}_3^{2-}$ is oxidized (forming SO_4^{2-}), while the left-hand atom is reduced (forming H_2S). The free energy available from the oxidation of thio-sulfate by *D. sulfodismutans* is insufficient to couple to substrate-level phosphorylation and so instead is coupled to a proton “pump” that uses the minimal energy available in the reaction to establish a proton motive force. Other partially reduced sulfur compounds such as sulfite (SO_3^{2-}) and sulfur (S^0) can also be disproportionated.

At least one sulfate-reducing bacterium can couple phosphite (HPO_3^-) oxidation to SO_4^{2-} reduction. This bacterium, *Desulfotignum phosphitoxidans*, is an autotroph and also a strict anaerobe. The chemolithotrophic reaction carried out by *D. phosphitoxidans* yields phosphate and sulfide:

The natural sources of phosphite are likely to be organophosphorous compounds called *phosphonates* that are generated from the anoxic degradation of nucleic acids, phospholipids, and other cellular sources. Along with sulfur respiration, sulfur disproportionation (also a chemolithotrophic process), and H_2 utilization, phosphite oxidation underscores the diversity of metabolic reactions carried out by sulfate-reducing bacteria.

Check Your Understanding

- What mechanisms do sulfate reducers use to balance electron flow and conserve energy when growing on organic substrates such as lactate?
- Why is cytochrome c_3 so important for energy conservation in sulfate-reducing bacteria?
- What difference in metabolism allows some sulfate reducers to oxidize organic carbon substrates all the way to CO_2 while others stop at acetate?

14.13 Other Electron Acceptors

Bacteria can perform a wide diversity of anaerobic respirations (Figure 14.1) including the respiration of several metals, metalloids, and associated minerals. In addition, certain organic and halogenated compounds can also serve as important electron acceptors in anaerobic respiration. We consider these forms of anaerobic respiration here.

Metal and Metalloid Reduction

A variety of metals, metalloids (elements such as arsenic, As, whose properties are intermediate between those of a metal and a non-metal), and associated minerals can be reduced through anaerobic respiration. Ferric iron (Fe^{3+}) and manganic ion (Mn^{4+}) are the most common such electron acceptors, but other possible electron acceptors include As^{5+} , Co^{3+} , Cr^{6+} , Se^{6+} , Tc^{7+} , Te^{6+} , U^{6+} . The reduction potential of the $\text{Fe}^{3+}/\text{Fe}^{2+}$ couple is +0.2 V (at pH 7), and that of the $\text{Mn}^{4+}/\text{Mn}^{2+}$ couple is +0.8 V; thus, several electron donors can couple to Fe^{3+} and Mn^{4+} reduction. A major challenge for metal-reducing organisms is that oxidized minerals of Fe and Mn are often insoluble, making transport into the cell difficult if not impossible. Hence, cells performing metal respiration need a mechanism for exporting electrons outside of the cell to allow the reduction to occur on the outer cell surface.

A number of different systems have evolved in diverse bacteria for reducing extracellular insoluble substrates. One well-studied example is *Geobacter sulfurreducens*, a gram-negative bacterium that can couple the oxidation of H_2 , acetate, or other organic electron donors to the reduction of a number of different metals and minerals (► Section 15.13). *G. sulfurreducens* can oxidize acetate using the citric acid cycle (◄ Section 3.6), and electrons make their way to electron transport by way of NADH. The electrons pass through quinones and are used to generate a pmf before reducing *c*-type cytochromes in the periplasm. These periplasmic cytochromes transfer electrons to a transmembrane porin–cytochrome complex embedded in the outer membrane. Finally, the electrons are transferred to specialized type IV pili (◄ Section 2.6) that are electrically conductive (Figure 14.31). These electrically conductive type IV pili are called **nanowires** because they function like electrical wires. The pili are enriched in aromatic amino acids that function to conduct electrons. Attached to the pili are multiheme *c*-type cytochromes that function as an adaptor to allow electrons to flow out of the pili and into an insoluble terminal electron acceptor, such as ferrihydrite (Fe_2O_3).

Other inorganic substances can function as electron acceptors for anaerobic respiration, including the metalloids selenium, tellurium, and arsenic, and various oxidized chlorine compounds (some of these are shown in Figure 14.1). For example, the sulfate-reducing bacterium *Desulfotomaculum auripigmentum* can reduce AsO_4^{3-} to AsO_3^{3-} , and sulfate to sulfide, precipitating the yellow mineral orpiment (As_2S_3) in the process (Figure 14.32). This process is an example of **biomineralization**, the formation of a mineral by bacterial activity. The presence of soluble forms of arsenic in groundwater is a major problem in many parts of the world and so microbes that convert arsenic from a soluble to an insoluble form provide a means of detoxifying contaminated habitats. Metal- and metalloid-reducing bacteria are of great importance in groundwater chemistry, and their metabolic activities are often used to remediate contaminated sites (► Section 22.3).

Figure 14.31 Iron-reducing bacteria reduce extracellular electron acceptors. Iron oxides are insoluble and cannot be transported into the cell. The bacterium *Geobacter* makes electrically conductive type IV pili (nanowires) that transfer electrons out of the cell where they reduce oxidized iron minerals.

Figure 14.32 Biomineralization during arsenate reduction by the sulfate-reducing bacterium *Desulfotomaculum auripigmentum*. Left, appearance of culture bottle after inoculation. Right, following growth for 2 weeks and biomineralization of arsenic trisulfide, As_2S_3 , also called orpiment. Center, synthetic sample of As_2S_3 .

Organic and Halogenated Electron Acceptors

Certain organic compounds can be electron acceptors in anaerobic respirations. Of those listed in Figure 14.1, the compound that has been most extensively studied is *fumarate*, a citric acid cycle intermediate that is reduced to succinate; the reaction in this anaerobic respiration is the opposite of the reaction that takes place in the citric acid cycle aerobically (◄ Figure 3.12). The role of fumarate as an electron acceptor for anaerobic respiration derives from the fact that the fumarate/succinate couple has a reduction potential near 0 V, which allows coupling of fumarate reduction to the oxidation of NADH, FADH, or H_2 . Many facultatively aerobic bacteria can grow anaerobically on fumarate as electron acceptor, including *Escherichia coli*.

Trimethylamine oxide (TMAO) and dimethyl sulfoxide (DMSO) (Figure 14.1) are also important organic electron acceptors. TMAO is a product of marine fish, and several bacteria can reduce it to trimethylamine (TMA), which has a strong odor and flavor (the odor of spoiled seafood is due primarily to TMA produced by bacterial action). Dimethyl sulfoxide (DMSO), which is reduced to dimethyl sulfide (DMS), is a common natural product and is found in both marine and freshwater environments. The reduction potentials of the TMAO/TMA and DMSO/DMS couples are about the same (near +0.15 V, Figure 14.1) and so the electron transport chains that terminate with TMAO or DMSO reductases typically contain cytochromes of the *b* type.

Several halogenated organic compounds function as electron acceptors in **reductive dechlorination** (also called *dehalorespiration*). For example, the sulfate-reducing bacterium *Desulfomonile* grows anaerobically with H_2 or organic electron donors and chlorobenzoate as an electron acceptor that is reduced to benzoate and hydrochloric acid (HCl):

Several other anaerobic bacteria can reductively dechlorinate, and some specialize in the use of chlorinated compounds as electron acceptors for anaerobic respiration. For example, *Dehalobacter* and *Dehalococcoides* oxidize H_2 and reduce tetrachloroethylene (TCE) to dichloroethylene and ethene, respectively. *Dehalococcoides* can also

reduce polychlorinated biphenyls (PCBs). TCE and PCBs are widespread organic pollutants that seep into groundwater and freshwater environments from underground storage tanks, leaking transformers, and other human inputs. However, removal of the chlorine groups from these molecules greatly reduces their toxicity and hence reductive dechlorination is not only a form of anaerobic respiration but also an environmentally significant process of bioremediation (► Sections 22.3–22.5).

We now explore the fascinating metabolisms of species of *Bacteria* and *Archaea* that specialize in the transformations of compounds that contain only one carbon: the C_1 metabolizers.

Check Your Understanding

- With H_2 as electron donor, why is reduction of Fe^{3+} a more favorable reaction than reduction of fumarate?
- Explain two different processes of anaerobic respiration that can be used to remediate contaminated environments.
- How can bacteria transfer electrons to an insoluble extracellular electron acceptor?

V • One-Carbon (C_1) Metabolism

Acetogenesis and methanogenesis are energy-conserving metabolisms that exploit exergonic reductions of CO_2 to form acetate and methane, respectively. Methanotrophs oxidize CH_4 while methylotrophs oxidize C_1 compounds other than CH_4 .

Carbon dioxide (CO_2) and methane (CH_4) are abundant in many anoxic habitats, and a wide diversity of microbes have evolved metabolic pathways that conserve energy from either the reduction of CO_2 or the oxidation of CH_4 . A number of the enzymatic reactions in one-carbon metabolisms are unique. In this part of the chapter, we consider the metabolism of organisms that either consume or produce C_1 compounds, highlighting the major similarities and differences.

14.14 Acetogenesis

Two major groups of strictly anaerobic microbes use CO_2 as an electron acceptor for energy conservation. One of these is the *acetogens*, and we discuss them here. The other group, the *methanogens*, are considered in the next section. Hydrogen (H_2) is a major electron donor for both groups of organisms, and an overview of their energy metabolism, **acetogenesis** and **methanogenesis**, is shown in Figure 14.33. Both processes are linked to ion pumps, of either protons (H^+) or sodium ions (Na^+), as the mechanism of energy conservation, and these pumps fuel ATP synthases in the membrane. The pathway of acetogenesis also conserves energy in a substrate-level phosphorylation reaction.

Organisms and Pathway

Acetogens carry out the reaction

In addition to H_2 , electron donors for acetogenesis include various C_1 compounds such as methanol, several methoxylated aromatic

Figure 14.33 The contrasting processes of methanogenesis and acetogenesis. Note the difference in free energy released in the reactions.

compounds, sugars, organic and amino acids, alcohols, and certain nitrogen bases, depending on the organism. Many acetogens can also grow by fermentation or by the anaerobic respiration of nitrate (NO_3^-) or thiosulfate ($S_2O_3^{2-}$). However, CO_2 reduction is a major feature of the acetogenic lifestyle, with CO_2 serving both as electron acceptor and as an intermediate through which carbon is assimilated into cellular material.

A major unifying thread among acetogens is the pathway of CO_2 reduction. Acetogens reduce CO_2 to acetate by the reductive acetyl-CoA pathway (also called the *Wood–Ljungdahl pathway*), the major pathway in obligate anaerobes for CO_2 fixation and the production of acetate (Section 14.2). The reactions of the reductive acetyl-CoA pathway are reversible, and some microbes reverse this pathway to oxidize acetate.

Acetogens such as *Acetobacterium woodii* and *Clostridium acetivum* can grow either chemoorganotrophically by fermentation of sugars (reaction A) or chemolithotrophically and autotrophically through the reduction of CO_2 to acetate with H_2 as electron donor (reaction B). In either case, the sole organic product is *acetate*:

When growing on glucose, acetogens use glycolysis (◀ Figure 3.11) to oxidize the glucose into two molecules of pyruvate and two molecules of NADH. The pyruvate is then further oxidized to produce two molecules of acetate:

The CO_2 generated in reaction (C) is then used as a terminal electron acceptor in the reductive acetyl-CoA pathway. The NADH generated during glycolysis and pyruvate oxidation is used as an electron donor in CO_2 reduction. Starting from pyruvate, then, the overall production of acetate can be written as

Most acetogenic bacteria that produce acetate in energy metabolism are gram-positive *Bacteria*, and many are species of the genera *Clostridium* or *Acetobacterium*. A few other gram-positive and many different gram-negative *Bacteria* and *Archaea* use the reductive acetyl-CoA pathway for autotrophic purposes, reducing CO_2 to acetate as a source of cell carbon; these include autotrophic sulfate-reducing bacteria (Section 14.12), anammox bacteria (Section 14.10), and

methanogens (Section 14.15). And finally, some microbes run the acetyl-CoA pathway in the *reverse direction* as a means of oxidizing acetate to CO_2 ; these include acetate-utilizing methanogens and sulfate-reducing bacteria. The acetyl-CoA pathway is thus a metabolically highly versatile series of reactions.

The Reductive Acetyl-CoA Pathway and Energy Conservation in Acetogenesis

Unlike other autotrophic pathways (Section 14.2), the reductive acetyl-CoA pathway of CO_2 fixation is not a cycle. Instead, it catalyzes the reduction of CO_2 along two linear pathways, with one molecule of CO_2 being reduced to the methyl group of acetate (the methyl branch of the pathway) and the other to the carbonyl group of acetate (the carbonyl branch of the pathway). These two C_1 units are then combined to form acetyl-CoA (Figure 14.34).

A key enzyme of the acetyl-CoA pathway is *carbon monoxide dehydrogenase*. CO dehydrogenase contains Ni, Zn, and Fe as cofactors and catalyzes the reaction

The CO produced by CO dehydrogenase ends up as the *carbonyl carbon* of acetate (reaction 1 in Figure 14.34). The methyl group of

acetate originates from the reduction of CO_2 by a series of reactions in which the coenzyme *tetrahydrofolate* (THF) plays a major role (Figure 14.34). The methyl group is then transferred from tetrahydrofolate to a cobalt- and iron-containing *corrinoid iron-sulfur protein* (CoFeSP) coenzyme. In the final step of the pathway, the methyl group is combined with CO by the activity of both CO dehydrogenase and acetyl-CoA synthase to form acetyl-CoA. Conversion of acetyl-CoA to acetate by the combined activities of the enzymes phosphotransacetylase and acetate kinase is the last step in the pathway, generating one ATP by substrate-level phosphorylation (Figure 14.34; see Table 14.5). However, this ATP is consumed in the first step of the acetyl-CoA pathway. Considering this, how then do acetogens get their ATP?

Acetogens conserve energy by the generation of an ion motive force. In *Acetobacterium woodii*, the best-studied acetogen, the ion motive force is generated by activity of the *Rnf complex*; this enzyme uses reduced ferredoxin (Fd_{red}) as electron donor and NAD^+ as electron acceptor. The Rnf complex pumps one Na^+ across the membrane for each electron exchanged, thereby generating a Na^+ motive force, which can be used to make ATP using a Na^+ -dependent ATP synthase (Figure 14.34). Alternatively, other acetogens such as *Clostridium ljungdahlii* use a proton motive force instead of a sodium

Figure 14.34 Reactions of acetogenesis from H_2 and CO_2 in *Acetobacterium woodii*. The reductive acetyl-CoA pathway is used to reduce CO_2 to acetate. The pathway has a methyl branch (blue arrows) and a carbonyl branch (red arrows). Carbon monoxide from the carbonyl branch and a methyl group from the methyl branch are combined into acetyl-CoA by carbon monoxide dehydrogenase ①, a key enzyme for the pathway. Note that the reductive acetyl-CoA pathway itself does not conserve energy. An electron-bifurcating hydrogenase ② (see also Figure 14.2) is used to reduce ferredoxin (Fd_{red}), and energy is conserved at the Rnf complex ③, which generates a Na^+ motive force. THF, tetrahydrofolate; CoFeSP, Co/Fe-containing corrinoid iron-sulfur protein.

motive force. The Fd_{red} required by the Rnf cluster is provided by a flavin-based electron bifurcation reaction (Figure 14.2) in which the oxidation of 2H_2 is coupled to the reduction of one Fd_{ox} and one NAD^+ (Figure 14.34). This bifurcation reaction is critical for producing the reduced ferredoxin required to conserve energy during acetogenic growth on H_2 . Ultimately, only 0.3 ATP are produced for every 4 H_2 and 2 CO_2 that are consumed by the acetogens, making these organisms minimalists in terms of the energy that can be conserved from their metabolism.

As we have seen, acetogens start with a C_1 or C_6 compound and make a C_2 product in acetate. We now examine methanogens, whose metabolism starts with a C_1 or C_2 (or rarely a C_3) compound and makes a C_1 product, natural gas (CH_4).

Check Your Understanding

- What is the purpose of CO dehydrogenase?
- If acetogens conserve energy using the Rnf complex, then what is the purpose of the reductive CoA pathway?
- What is electron bifurcation and what role does it play in acetogens?

14.15 Methanogenesis

The biological production of methane—*methanogenesis*—is catalyzed by a diverse assemblage of strictly anaerobic *Archaea* called the **methanogens**. These organisms are common in freshwater sediments and wetlands (Figure 14.35), the guts of many animals including humans, sewage sludge digesters (► Section 22.8), and other bioreactors. The reduction of CO_2 by H_2 to form CH_4 is a major pathway of methanogenesis and is a form of anaerobic respiration. We consider the basic properties, phylogeny, and taxonomy of the

methanogens in Section 17.2. Here we focus on their bioenergetics and unique biochemistry.

C_1 Carriers in Methanogenesis

Methanogenesis from CO_2 requires eight electrons, and these electrons are added two at a time. This leads to intermediary oxidation states of the carbon atom from +4 (CO_2) to −4 (CH_4). Several novel coenzymes participate in methanogenesis and can be divided into two classes: (1) those that carry the C_1 unit along its path of enzymatic reduction (*C_1 carriers*) and (2) those that donate electrons (*redox coenzymes*) (Figure 14.36). We consider the C_1 carriers first.

The coenzyme *methanofuran* (MF) is required for the first step of methanogenesis. Methanofuran contains the five-membered furan ring and an amino nitrogen atom that binds CO_2 (Figure 14.36a). *Methanopterin* (MP, Figure 14.36b, also called *tetrahydromethanopterin*) is a methanogenic coenzyme that resembles the vitamin folic acid and plays a role analogous to that of tetrahydrofolate (see Figure 14.34) by carrying the C_1 unit in the intermediate steps of CO_2 reduction to CH_4 . *Coenzyme M* (CoM) (Figure 14.36c) is required for the terminal step of methanogenesis, the reduction of the methyl group ($-\text{CH}_3$) to CH_4 . Although not a C_1 carrier, the nickel (Ni^+)-containing tetrapyrrole *coenzyme F₄₃₀* (Figure 14.36d) also participates in the terminal step of methanogenesis as part of the methyl reductase enzyme complex (discussed later).

Redox Coenzymes

The coenzymes F_{420} and 7-mercaptoheptanoylthreonine phosphate (also called coenzyme B, CoB) are electron donors in methanogenesis. Coenzyme F_{420} (Figure 14.36e) is a flavin derivative, structurally resembling the flavin coenzyme FMN (◀ Figure 3.15). F_{420} participates in methanogenesis as the electron donor in several steps of CO_2 reduction (see Figure 14.38). Coenzyme F_{420} takes its name from the fact that its oxidized form absorbs light at 420 nm and fluoresces blue-green. Such fluorescence is useful for the microscopic identification of a methanogen (Figure 14.37). CoB is required for the terminal step of methanogenesis catalyzed by the *methyl reductase enzyme complex*. As shown in Figure 14.36f, the structure of CoB resembles the vitamin pantothenic acid, which is part of acetyl-CoA (◀ Figure 3.8).

Methanogenesis from $\text{CO}_2 + \text{H}_2$

Nearly all methanogens can use H_2 as the source of electrons for the reduction of CO_2 to CH_4 . Some can also use a few additional substrates including acetate, formate, methanol, and methylamines. Methanogens use the reductive acetyl-CoA pathway (Sections 14.2 and 14.14) to assimilate CO_2 into cellular material. With respect to energy conservation, two major groups of methanogens are differentiated by the presence or absence of cytochromes. We will first consider methanogenesis from H_2 and CO_2 in methanogens that lack cytochromes (Figure 14.38):

1. CO_2 is activated by a methanofuran-containing enzyme and reduced to the formyl (CHO) level. The immediate electron donor is ferredoxin (Fd_{red}), a strong reductant with a reduction potential (E_0') of about −0.45 V.

The atoms shaded in brown or yellow are the sites of oxidation–reduction reactions (brown in F₄₂₀ and CoB) or the position to which the C₁ moiety is attached during the reduction of CO₂ to CH₄ (dark yellow in methanofuran, methanopterin, and coenzyme M). The same colors used to highlight a particular coenzyme name (CoB is orange, for example) are also used in Figures 14.38 and 14.39 to follow the reactions in each figure. Coenzyme F₄₃₀ participates in the terminal step of methanogenesis catalyzed by the enzyme methyl reductase, with the methyl group binding to Ni⁺ in F₄₃₀ prior to its reduction to CH₄.

Figure 14.37 Fluorescence due to the methanogenic coenzyme F_{420} . (a) Auto-fluorescence in cells of the methanogen *Methanosarcina barkeri* due to the presence of the unique electron carrier F_{420} . A single cell is about $1.7\ \mu\text{m}$ in diameter. The organisms were made visible by excitation with blue light in a fluorescence microscope. (b) F_{420} fluorescence in cells of the methanogen *Methanobacterium formicum*. A single cell is about $0.6\ \mu\text{m}$ in diameter.

- The formyl group is transferred from methanofuran (MF) to an enzyme containing methanopterin (MP). It is subsequently dehydrated and reduced in two separate steps (total of 4 H) to the methylene and methyl levels. The 2 H required for each of these reductions are derived from H_2 and transferred by F_{420} .
- The methyl group is transferred from MP to an enzyme containing CoM by the enzyme methanopterin:coenzyme M methyl-transferase. This highly exergonic reaction results in energy conservation because it drives $2\ Na^+$ across the membrane, resulting in the formation of a sodium motive force.
- Methyl-S-CoM is reduced to CH_4 by methyl-coenzyme M reductase. In this reaction, F_{430} and CoB are required. Coenzyme F_{430} removes the CH_3 group from CH_3 -S-CoM, forming a Ni^+-CH_3 complex. This complex is reduced by CoB, generating CH_4 and a heterodisulfide bond between CoM and CoB (CoM-S-S-CoB).

Figure 14.38 Methanogenesis from CO_2 plus H_2 . The carbon atom reduced is highlighted in green, and the source of electrons is highlighted in brown. See Figure 14.36 for the structures of the coenzymes. Methanogens without cytochromes reduce the heterodisulfide bond in CoM-S-S-CoB using an electron bifurcation reaction (red box and reaction arrow) that also generates reduced ferredoxin (Fd_{red}). Methanogens with cytochromes conserve more energy by using CoM-S-S-CoB as the electron acceptor in electron transport (blue box and arrow). MF, methanofuran; MP, methanopterin; CoM, coenzyme M; $F_{420}H_2$, reduced coenzyme F_{420} ; F_{430} , coenzyme F_{430} ; Fd, ferredoxin; CoB, coenzyme B; M, methanophenazine.

5. Free CoM and CoB are regenerated by the reduction of CoM-S—S-CoB ($E_0' = -0.14$) catalyzed by heterodisulfide reductase through a flavin-based electron-bifurcation reaction (see red-shaded region in Figure 14.38; see also Figure 14.2) with H_2 (-0.42 V) as the electron donor. The high reduction potential of CoM-S—S-CoB is used to drive electrons in the bifurcation reaction to reduce ferredoxin. The Fd_{red} so generated is then used for CO_2 reduction in the first step of the pathway.

Under standard conditions, the free energy of methanogenesis from $H_2 + CO_2$ is -131 kJ/mol; however, the free energy available under natural conditions is likely in the range of -17 to -40 kJ/mol. In methanogens that lack cytochromes, a sodium motive force drives ATP formation by activity of a Na^+ -linked ATPase. The heterodisulfide reductase reaction produces a net of two H^+ in the cytoplasm and these are exchanged for one Na^+ by an $H^+ : Na^+$ antiporter in the membrane (Figure 14.38). Hence, the production of one CH_4 molecule from $H_2 + CO_2$ yields a net of one Na^+ ion pumped across the membrane, sufficient to form less than 0.5 ATP.

In methanogens containing cytochromes, H_2 is oxidized at a membrane-bound hydrogenase containing *b*-type cytochromes. This enzyme passes electrons to a membrane-associated electron carrier called *methanophenazine* (M, highlighted in blue in Figure 14.38). Methanophenazine in turn passes electrons to a membrane-bound heterodisulfide reductase complex that reduces CoM-S—S-CoB (Figure 14.38). The net result of these electron transport reactions is the generation of a pmf. Methanogens with cytochromes have H^+ -linked ATPases in place of the Na^+ -fueled ATPases found in many other methanogens. Since Fd_{red} is still required for CO_2 reduction, some of the pmf drives Fd_{red} formation using electrons from H_2 (Figure 14.38). The net result is that methanogens with cytochromes conserve more energy than those without, forming >1 ATP per molecule of CH_4 formed from $H_2 + CO_2$.

In methanogens we thus see at least two mechanisms for energy conservation that have different energy yields: (1) a sodium motive force (which can be converted to a proton motive force) linked to the methyl transferase reaction, and (2) a proton motive force linked to cytochrome-dependent electron transport reactions. In addition to these energetic differences, cytochrome-containing methanogens

are more metabolically versatile than those that lack cytochromes, with many species able to metabolize acetate, methanol, and other methylated compounds, as we see next.

Methanogenesis from Methyl Compounds and Acetate

Cytochrome-containing methanogens, such as *Methanosarcina*, can form CH_4 from acetate and certain methylated compounds, as well as from $H_2 + CO_2$. Methyl compounds such as methanol are catabolized by donating methyl groups to an enzyme containing a corrinoid coenzyme to form CH_3 -corrinoid. Corrinoids are the parent structures of compounds such as vitamin B_{12} and contain a porphyrin-like ring with a central cobalt atom. The CH_3 -corrinoid complex then transfers the methyl group to CoM, yielding CH_3 -S-CoM (Figure 14.39a). Energy is then conserved during electron transport reactions in the same manner as for growth on $H_2 + CO_2$ (Figure 14.38). However, in the absence of H_2 , the reducing power for driving electron transport reactions comes from running the methanogenic pathway in reverse from CH_3 -S-CoM to produce CO_2 , one molecule of Fd_{red} , and two molecules of $F_{420}H_2$. These reduced $F_{420}H_2$ molecules can donate electrons to the electron transport chain in place of H_2 (Figure 14.39a). In addition, the Fd_{red} can be oxidized by an energy-converting hydrogenase (see Section 14.12) to produce H_2 (which can donate electrons to the electron transport chain along with $F_{420}H_2$) and contribute further to pmf formation. The net result for growth on methanol is that one molecule of methanol must be oxidized to CO_2 for every three reduced to CH_4 .

When acetate is the substrate for methanogenesis by acetate-degrading methanogens (called *acetoclastic methanogens*), it is first activated to acetyl-CoA, which interacts with CO dehydrogenase from the acetyl-CoA pathway (Section 14.14 and Figure 14.34). The methyl group of acetate is then transferred to the corrinoid enzyme, ultimately forming CH_3 -MP (Figure 14.39b). Formation of CH_4 from CH_3 -MP proceeds as in the $H_2 + CO_2$ pathway (Figure 14.38), resulting in the formation of both a Na^+ and a H^+ motive force. Simultaneously, the CO group is oxidized to yield CO_2 and Fd_{red} (Figure 14.39b). The reduced ferredoxin can be oxidized by an energy-converting hydrogenase (see Figure 14.43) to produce H_2 and contribute further to pmf formation.

Figure 14.39 Methanogenesis from methanol and acetate. Both reactions funnel carbon into the methanogenic pathway (Figure 14.38) but at different points. (a) For growth on methanol (CH_3OH), redox balance is achieved because one CH_3OH is oxidized to CO_2 for every 3 reduced to CH_4 . (b) Acetate is split into CH_4 and CO_2 . Abbreviations and color-coding are as in Figures 14.36 and 14.38; CODH, carbon monoxide dehydrogenase.

Autotrophy

Autotrophy in methanogens is supported by the reductive acetyl-CoA pathway (Sections 14.2 and 14.14). As we have just seen, parts of this pathway are already integrated into the catabolism of methanol and acetate by methanogens that contain cytochromes (Figure 14.39). However, methanogens lack the tetrahydrofolate-driven series of reactions of the acetyl-CoA pathway that lead to the production of a methyl group (Figure 14.34). But this is not a problem because methanogens produce methyl groups during methanogenesis from H_2 and CO_2 . In addition, methylotrophic methanogens derive the required methyl groups directly from their electron donors. Finally, acetoclastic methanogens have no need for CO_2 fixation because acetyl-CoA, which is formed during acetate oxidation (Figure 14.39b), can be funneled directly into biosynthesis.

Check Your Understanding

- Why is it that methanogens lacking cytochromes are unable to form CH_4 from methyl compounds?
- Explain why methanogens that contain cytochromes can conserve more energy than those that lack cytochromes.
- Explain how a reaction that produces a free energy yield of less than -31.8 kJ/mol, and produces a net translocation of just a single Na^+ ion, is enough to drive the formation of ATP.

14.16 Methanotrophy

Methane (CH_4) and many other C_1 organic compounds can be catabolized both aerobically and anaerobically. In this section, we consider the oxidation of these compounds by **methylotrophs**, organisms that use organic compounds that lack $C-C$ bonds as electron donors and carbon sources. The oxidations of CH_4 and methanol (CH_3OH) have been the best-studied reactions, and we focus here on the oxidation of CH_4 as an example of a methylotrophic lifestyle.

Aerobic Methane Oxidation

Not all methylotrophs can use methane. **Methanotrophs** are those methylotrophs that can use CH_4 , and methanotrophy has been well studied in aerobic methanotrophs such as the gram-negative bacterium *Methylococcus capsulatus*. The steps in CH_4 oxidation to CO_2 can be summarized as

The initial step in the *aerobic* oxidation of CH_4 is catalyzed by the enzyme *methane monooxygenase* (MMO). Monooxygenases incorporate one oxygen atom from O_2 into a carbon compound (see Section 14.23 and Figure 14.54a). *M. capsulatus* contains two MMOs, one cytoplasmic (soluble MMO, sMMO) and the other membrane-integrated (particulate MMO, pMMO). In the MMO reaction, an atom of oxygen is introduced into CH_4 , forming CH_3OH , and the second atom of O is reduced to form H_2O . CH_3OH is oxidized to formaldehyde (CH_2O) and then to CO_2 , yielding NADH that can be used to conserve energy in electron transport to O_2 . In addition, formaldehyde can be siphoned off to provide carbon for biosynthesis through one of two different pathways.

C_1 Assimilation by Aerobic Methanotrophs

At least two distinct pathways exist for the incorporation of C_1 units into cell material in methanotrophs. The **serine pathway** is outlined in Figure 14.40a. In this pathway, acetyl-CoA is synthesized from one molecule of CH_2O and one molecule of CO_2 . The serine pathway requires reducing power and energy in the form of two molecules each of NADH and ATP, respectively, for each acetyl-CoA synthesized. The serine pathway employs a number of enzymes of the citric acid cycle and one enzyme, *serine transhydroxymethylase*, unique to the pathway (Figure 14.40a).

An alternative pathway for C_1 incorporation is the **ribulose monophosphate pathway** (Figure 14.40b). This pathway is more energy efficient than the serine pathway because *all* of the carbon for cell material is derived from CH_2O . Because CH_2O is at the same oxidation level as cell material, no reducing power is needed for its incorporation. Hence, all of the NADH from the oxidation of methane can be oxidized in the electron transport chain.

The ribulose monophosphate pathway consumes one molecule of ATP for each molecule of glyceraldehyde 3-phosphate (G-3-P) synthesized (Figure 14.40b); two G-3-Ps can then be converted into glucose by reversal of the glycolytic pathway (◀ Figure 3.11). Enzymes unique to the ribulose monophosphate pathway are *hexulosephosphate synthase*, which condenses one molecule of formaldehyde with one molecule of ribulose 5-phosphate, and *hexulose 6-P isomerase*, which forms fructose derivatives that can be converted into glyceraldehyde 3-P (Figure 14.40b). The remaining enzymes of this pathway are enzymes of intermediary metabolism widely distributed in bacteria.

Anaerobic Oxidation of Methane (AOM)

The *anaerobic* oxidation of methane uses a variety of enzymes and cofactors common to other forms of C_1 metabolism; however, anaerobic methanotrophy shows some novel features, as well. Methane can be oxidized anaerobically by a microbial association (called a *consortium*) of two organisms, a sulfate-reducing bacterium (SRB) plus a species of *Archaea* phylogenetically related to methanogens. These consortia thrive in anoxic marine sediments and are responsible for oxidizing more than 90% of the methane produced there. The components of the consortium coexist in spatially structured aggregates (Figure 14.41). The archaeal component, called ANME (*anaerobic methanotroph*), of which there are several different types, oxidizes CH_4 as an electron donor. Electrons from methane oxidation are then transferred to the sulfate reducer, which uses them to reduce SO_4^{2-} to H_2S (Figure 14.41b).

ANME *Archaea* oxidize CH_4 to CO_2 by reversing the steps of methanogenesis (Figure 14.38). This process is endergonic but is made possible by the SRB partner organism, which consumes electrons from ANME, thereby making the oxidation CH_4 to CO_2 energetically favorable. Remarkably, electrons are transferred between the ANME and SRB partners by *direct electron transfer* (Figure 14.41b, c). Cells of ANME make electrically conductive multiheme cytochromes that span their outer cell layer and transfer electrons from the cytoplasmic membrane to the outside of the cell. The SRB have similar large electrically conductive cytochromes as well as pili that serve as electrically conductive “nanowires” (Section 14.13). These pili can

Figure 14.40 The serine and ribulose monophosphate pathways for the assimilation of C_1 units into cell material by methylotrophic bacteria. (a) Serine pathway. The product, acetyl-CoA, is used as the starting point for making new cell material. The key enzyme of the pathway is serine transhydroxymethylase. (b) Ribulose monophosphate pathway. Three molecules of CH_2O are required, with the product being glyceraldehyde 3-phosphate. The key enzyme of this pathway is hexulosephosphate synthase. The sugar rearrangements require enzymes of the pentose phosphate pathway (◀ Figure 3.31).

The aggregates contain methane-oxidizing (methanotrophic) *Archaea* (red) surrounded by sulfate-reducing bacteria (green). Each cell type has been stained by a different FISH probe (▶ Section 19.5). The aggregate is about 30 μm in diameter. (b) Mechanism for the cooperative degradation of CH_4 . Electrons are transferred from the archaeal methanotrophic (ANME) cell to the sulfate reducer by direct electron transfer through the “nanowire” connections. (c) Transmission electron micrograph of a section through a methane-oxidizing aggregate showing an ANME cell transferring electrons to a sulfate reducer.

be more than 1 μm in length and electrically connect the cells within aggregates to facilitate the two microbes' metabolisms (Figure 14.41b, c; ► Section 23.3). Such direct electron transfer likely explains why some ANME can also use insoluble metals such as iron (Fe^{3+}) and manganese oxides (Mn^{4+}) as terminal electron acceptors (Section 14.13) in CH_4 oxidation. Since these insoluble materials cannot enter the cell, the cell has to "reach out" to them in order to transfer electrons.

AOM is not limited to consortia of ANME and SRB. ANME *Archaea* include *Methanoperedens nitroreducens*, which uses nitrate (NO_3^-) as a terminal electron acceptor for the anaerobic oxidation of CH_4 . This organism couples reverse methanogenesis to the reduction of NO_3^- to NO_2^- . *M. nitroreducens* can be found in consortia with denitrifying bacteria that then use NO_2^- as an electron acceptor. These consortia are active in anoxic environments where CH_4 and NO_3^- coexist, such as certain freshwater sediments.

Intra-Aerobic Methanotrophy

The methanotrophic denitrifying bacterium *Methylomirabilis oxyfera* is an obligate anaerobe that catalyzes AOM linked to NO_2^- as an electron acceptor. *M. oxyfera* can grow on CH_4 in pure culture and has a highly unusual polygonal morphology (Figure 14.42). Analysis of the *M. oxyfera* genome reveals all of the genes required for the aerobic oxidation of CH_4 to CO_2 . *M. oxyfera* is also able to reduce NO_2^- to N_2 , and it has most of the genes required for denitrification although it lacks nitric oxide reductase and nitrous oxide reductase (Section 14.11 and Figure 14.28). This leads to the interesting question of why an *anaerobic* bacterium would use *aerobic* pathways for CH_4 oxidation.

The answer to this conundrum is that *M. oxyfera* reduces nitrite in a novel way. The organism reduces NO_2^- to nitric oxide (NO) as a normal denitrifying bacterium would, but then *M. oxyfera* does something remarkable: The organism generates O_2 through the

reaction $2\text{NO} \rightarrow \text{N}_2 + \text{O}_2$ and proceeds to use this O_2 as the electron acceptor for CH_4 oxidation. Because *M. oxyfera* produces its own O_2 , its methanotrophic metabolism has been termed *intra-aerobic methanotrophy*. As it turns out, O_2 is toxic for the anaerobic *M. oxyfera*. However, if the O_2 is consumed (by its reduction to H_2O using electrons from the oxidation of CH_4) as soon as it is produced, O_2 never accumulates, and the organism's environment remains anoxic.

We transition to Part VI now and consider metabolisms in which ATP is not a product of electron transport reactions. These are the fermentations—metabolisms in which there is no lack of physiological diversity.

Check Your Understanding

- When using CH_4 as electron donor, why is *Methylococcus capsulatus* an obligate aerobe?
- In which two ways does the ribulose monophosphate pathway save energy over reactions of the serine pathway?
- What is unique about methanotrophy in *Methylomirabilis oxyfera*?

VI • Fermentation

Fermentations are anaerobic metabolisms that do not require external electron acceptors. Fermenting microbes achieve redox balance and conserve energy by forming various fermentation products that are excreted from the cell.

Thus far we have considered phototrophy and many types of aerobic and anaerobic respiration; these processes are unified by the fact that they all conserve energy primarily by using an ion gradient (H^+ or Na^+) that fuels photophosphorylation or oxidative phosphorylation. Here we turn our focus to *fermentation*, in which energy conservation depends primarily upon substrate-level phosphorylation reactions.

14.17 Energetic and Redox Considerations

Fermentation is a form of chemotrophic metabolism defined by the lack of an external electron acceptor. In fermentation, cells conserve energy primarily by substrate-level phosphorylation and they achieve redox balance by donating electrons to metabolic intermediates excreted as fermentation products. Fermentative organisms face two major challenges. First, their reliance on substrate-level phosphorylation means that they typically conserve much less energy than respiratory organisms. Second, their lack of external electron acceptors makes it difficult to achieve redox balance.

A tremendous diversity of fermentation reactions are possible. Many fermentative organisms, such as *Escherichia coli*, perform diverse metabolic reactions and only ferment when external electron acceptors are absent and conditions are anoxic. However, there are many more organisms, such as most lactic acid bacteria and the clostridia, which have exclusively fermentative metabolisms. Over the next few sections, we will see that fermentative organisms have evolved diverse strategies for facing the challenges of energy scarcity and redox balance.

Laura Van Niftrik and Mingliang Wu

Figure 14.42 The cell morphology of *Methylomirabilis oxyfera*. The denitrifying methanotroph *M. oxyfera* has a unique polygonal morphology as revealed in this transmission electron micrograph of cells from a microbial community grown in a bioreactor. A cell is about 0.5 μm in diameter.

Energy-Rich Compounds and Substrate-Level Phosphorylation

Energy can be conserved by substrate-level phosphorylation from many different compounds. However, as we learned in Chapter 3, central to an understanding of substrate-level phosphorylation is the concept of *energy-rich compounds* (◀ Figure 3.8). These are organic compounds that contain an energy-rich phosphate bond or a molecule of coenzyme A. The bond is “energy-rich” because its hydrolysis is highly exergonic. Table 14.5 lists some energy-rich compounds formed during metabolism; the hydrolysis of most of these yields sufficient free energy to be coupled to ATP synthesis ($\Delta G^{0'} = -31.8$ kJ/mol). If an organism can form one of these compounds during fermentative metabolism, it can make ATP by transferring the phosphate bond from the energy-rich compound to ADP to form ATP— in other words, substrate-level phosphorylation.

Many anaerobic bacteria produce acetate or other fatty acids as a major or minor fermentation product. The production of fatty acids offers the organism the opportunity to conserve energy by substrate-level phosphorylation. The key to this process is the production of a coenzyme-A derivative of the fatty acid, since these are energy-rich compounds (Table 14.5). For example, acetyl-CoA can be converted to acetyl phosphate and the phosphate group subsequently transferred to ADP, yielding ATP (see Figures 14.46 and 14.47). Fatty acid production is common in fermentations, and if the fatty acid is metabolized through a CoA intermediate, the potential for ATP synthesis by substrate-level phosphorylation is a possibility.

Achieving Redox Balance

In any fermentation there must be atomic and redox balance. That is, the total number of each type of atom and electrons in the

TABLE 14.5 Energy-rich compounds that can couple to substrate-level phosphorylation ^a	
Compound	Free energy of hydrolysis, $\Delta G^{0'}(\text{kJ/mol})^b$

^aData from Thauer, R.K., K. Jungermann, and K. Decker. 1977. Energy conservation in chemotrophic anaerobic bacteria. *Bacteriol. Rev.* 41: 100.
^bThe $\Delta G^{0'}$ values shown here are for “standard conditions,” which are not necessarily those of cells. Including heat loss, the energy costs of making an ATP are more like −60 kJ/mol than −31.8 kJ/mol, and the energy of hydrolysis of the energy-rich compounds shown here is thus likely higher. But for simplicity and comparative purposes, the values in this table will be taken as the actual energy released per reaction.

Formate hydrogenlyase

Hydrogenase (cytoplasmic)

Energy-converting hydrogenase (transmembrane)

Electron confurcation

Figure 14.43 Production of H₂ to achieve redox balance during fermentation. Several mechanisms exist for reducing protons to H₂, thereby allowing the cell to achieve redox balance by exporting electrons. Energy-converting hydrogenases allow for coupling of H₂ production with energy conservation by pumping an H⁺ across the membrane to generate a proton-motive force.

reaction products must balance those in the reactants (the substrates). Redox balance is achieved by the excretion of fermentation products, reduced substances such as acids or alcohols that are made as products of the fermentation. However, many reactions are difficult to balance, and so fermentative organisms have evolved alternative mechanisms for achieving redox balance.

In many fermentations, redox balance is facilitated by the production of molecular hydrogen (H₂). Fermentative organisms can produce H₂ in several ways (Figure 14.43). First, H₂ can be produced from the C₁ fatty acid formate using the enzyme *formate hydrogenlyase*. This mechanism is the source of fermentative H₂ production used by many facultative aerobes including most enteric bacteria such as *E. coli*. Second, H₂ can be produced from proton reduction using the iron–sulfur protein *ferredoxin* (Fd_{red}), in a reaction catalyzed by a *hydrogenase* enzyme. Many organisms perform this reaction using a membrane-bound *energy-converting hydrogenase* because this enzyme couples H₂ production to proton pumping, thereby contributing to pmf formation and energy conservation (Figure 14.43).

Finally, some organisms produce H₂ using electron confurcation (Figure 14.43, see also Section 14.1). The advantage of electron confurcation is that it provides the ability to regenerate NAD⁺ by producing H₂ from NADH at low energetic cost. Consider that $\Delta G^{0'} = +17$ kJ/mol for the confurcation reaction producing two H₂, while $\Delta G^{0'} = +20$ kJ/mol for the direct coupling of NADH to H₂ production; hence, confurcation allows the cell to produce two H₂ for less energy than it takes to produce one H₂ from the oxidation of NADH by reverse electron transport.

Fermentative organisms excrete H₂ to achieve redox balance by reoxidizing electron carriers such as NAD(P)H and Fd_{red}. The four mechanisms for H₂ production (Figure 14.43) all have $\Delta G^{0'}$ very close to zero under standard conditions. However, fermentation can produce copious amounts of NADH and Fd_{red} that would accumulate in the cell if these electron carriers were not reoxidized. Under actual physiological conditions, then, these H₂ production reactions are usually slightly exergonic, and in the case of energy-converting hydrogenases (Figure 14.43) can even be used to conserve energy. Another factor to consider is that H₂, excreted as a waste product by

fermentative organisms, is a very powerful electron donor for respiratory organisms, and this reality typically keeps H₂ levels in anoxic environments extremely low.

With H₂ we thus see that the waste product of one organism becomes a resource for another. This metabolic coupling, in which one organism's waste is another organism's resource, is a theme that runs throughout the microbial world. With these bioenergetic and redox principles in mind, we explore the metabolic diversity of fermentations beginning with species that produce acidic fermentation products, common and widespread bacteria in most anoxic environments.

Check Your Understanding

- Why is H₂ produced during many types of fermentation?
- Why is acetate formation in fermentation energetically beneficial to the cell?
- What is an energy-converting hydrogenase, and what role does it play in achieving redox balance?

14.18 Lactic and Mixed-Acid Fermentations

Fermentations are categorized by either the substrate fermented or the products formed. Table 14.6 lists some major fermentations classified on the basis of the products formed, such as alcohol, lactic acid, or other reduced organic compounds. Other fermentations are classified by the substrate fermented rather than the fermentation product; for instance, the amino acid, purine/pyrimidine, or succinate fermentations. We begin with two very common fermentations of sugars in which lactic acid is the sole or major product.

Lactic Acid Fermentation

Lactic acid bacteria are gram-positive nonsporulating bacteria that produce lactic acid as a major or sole fermentation product from the fermentation of sugars (► Section 16.6). Two fermentative patterns are observed. One, called **homofermentative**, yields a single fermentation product, lactic acid. The other, called

heterofermentative, yields products in addition to lactate, mainly ethanol plus CO₂.

Figure 14.44 summarizes pathways for the fermentation of glucose by homofermentative and heterofermentative lactic acid bacteria. The differences observed can be traced to the presence or absence of the enzyme *aldolase*, a key enzyme of glycolysis (◄ Figure 3.11). Homofermentative lactic acid bacteria contain aldolase and produce *two* molecules of lactate from glucose by the glycolytic pathway (Figure 14.44a). Heterofermenters lack aldolase and thus cannot break down fructose biphosphate to triose phosphate. Instead, they oxidize glucose 6-phosphate to 6-phosphogluconate and then decarboxylate this to ribulose 5-phosphate and on to xylulose 5-phosphate. The latter is then converted to triose phosphate and acetyl phosphate by the key enzyme *phosphoketolase* (Figure 14.44b). The early steps in catabolism by heterofermentative lactic acid bacteria are those of the pentose phosphate pathway (◄ Figure 3.31).

In heterofermenters, triose phosphate is converted to lactic acid with the production of ATP (Figure 14.44b). However, to achieve redox balance the acetyl phosphate produced is used as an electron acceptor and is reduced by NADH (generated during the production of pentose phosphate) to ethanol. This occurs without ATP synthesis because the energy-rich CoA bond is lost during ethanol formation. Because of this, heterofermenters produce only *one* ATP per glucose instead of the *two* ATP per glucose produced by homofermenters. In addition, because heterofermenters decarboxylate 6-phosphogluconate, they produce CO₂ as a fermentation product; homofermenters do not produce CO₂. Thus, an easy way to differentiate a homofermenter from a heterofermenter is to observe for the production of CO₂ in laboratory cultures.

Entner–Doudoroff Pathway

The initial stages of glucose fermentation often rely on glycolysis (◄ Figure 3.11) or a variant of the glycolytic pathway called the *Entner–Doudoroff pathway* (this variation is shown in Figure 14.44b). In the Entner–Doudoroff pathway, glucose 6-phosphate is oxidized to 6-phosphogluconic acid and NADPH; the 6-phosphogluconic

(a) Homofermentative

(b) Heterofermentative

Figure 14.44 The fermentation of glucose in (a) homofermentative and (b) heterofermentative lactic acid bacteria. Note that no ATP is made in reactions leading to ethanol formation in heterofermentative organisms.

acid is dehydrated and split into pyruvate and glyceraldehyde 3-phosphate (G-3-P), a key intermediate of the glycolytic pathway. G-3-P is then catabolized as in glycolysis, generating NADH and two ATP, and used as an electron acceptor to balance redox reactions as occurs in both lactic acid fermentations (Figure 14.44).

Because pyruvate is formed directly in the Entner–Doudoroff pathway and cannot yield ATP as can G-3-P (Figure 14.44), the Entner–Doudoroff pathway yields only half the ATP of the glycolytic pathway. Organisms using the Entner–Doudoroff pathway therefore share this physiological characteristic with heterofermentative lactic acid bacteria (Figure 14.44b). *Zymomonas*, an obligately fermentative gram-negative bacterium, and *Pseudomonas*, a strictly respiratory bacterium (► Section 16.4), are major genera that employ the Entner–Doudoroff pathway for glucose catabolism, although a modified version of this pathway is present in some species of hyperthermophilic and extremely halophilic *Archaea*.

Mixed-Acid Fermentations

In *mixed-acid fermentations* (Table 14.6), characteristic of enteric bacteria such as *Escherichia coli* and relatives (► Section 16.3), three different acids—*acetic*, *lactic*, and *succinic*—are formed from the fermentation of glucose or other sugars that can be converted into glucose. Ethanol, CO₂, and H₂ are also typically formed as fermentation products. Glycolysis (◄ Figure 3.11) is the pathway used to degrade glucose by mixed-acid fermenters.

Some enteric bacteria produce acidic products in lower amounts than *E. coli* and balance redox in their fermentations by producing larger amounts of neutral products. One key neutral product is the four-carbon alcohol *butanediol*. In this variation of the mixed-acid fermentation, the main products observed are butanediol, ethanol, CO₂, and H₂ (Figure 14.45). In the mixed-acid fermentation of *E. coli*, equal amounts of CO₂ and H₂ are produced, whereas in a

Figure 14.45 Butanediol production and mixed-acid fermentations. Note how only one NADH but two molecules of pyruvate are used to make one butanediol. This leads to redox imbalance and the production of more ethanol by butanediol producers than by mixed-acid fermenters. A yellow highlight is used to show the path that two of the four pyruvate carbons take to end up in α -acetolactate.

butanediol fermentation, considerably more CO_2 than H_2 is produced. This is because mixed-acid fermenters produce CO_2 only from formic acid by means of the enzyme *formate hydrogenlyase* (Figure 14.45, see also Figure 14.43):

By contrast, butanediol producers, such as *Enterobacter aerogenes*, produce CO_2 and H_2 from formic acid but also produce two additional molecules of CO_2 during the formation of each molecule of butanediol. However, because butanediol production consumes only one-half of the NADH generated in glycolysis, more ethanol is produced by these organisms than by non-butanediol fermenters in order to achieve redox balance (Figure 14.45).

Lactic acid and enteric bacteria are facultative, meaning that they can grow either aerobically or anaerobically. By contrast, some fermenters are obligate anaerobes and we explore their fermentation patterns now.

Check Your Understanding

- How can homo- and heterofermentative metabolism be differentiated in pure cultures of lactic acid bacteria?
- Why does butanediol production lead to greater ethanol production than the mixed-acid fermentation of *Escherichia coli*?
- How and why does *E. coli* produce H_2 during fermentation?

14.19 Fermentations of Obligate Anaerobes

Many fermentative organisms are obligate anaerobes. These organisms grow under highly reducing conditions, often use enzymes that cannot tolerate O_2 , and often produce H_2 as a fermentation product. Species of *Clostridium* (► Section 16.8) and their relatives are the most well known of this group. Different species of clostridia ferment different groups of substrates, including sugars, amino acids, purines and pyrimidines, and a few other compounds. In all cases, ATP synthesis is linked primarily to substrate-level phosphorylation.

However, we will see that many obligately anaerobic fermentative organisms can also conserve some energy through the generation of pmf. We begin with *saccharolytic* (sugar-fermenting) clostridia.

Sugar Fermentation by *Clostridium* Species

A number of clostridia ferment sugars, producing *butyric acid* and H_2 as major fermentation products. A generalized scheme for the biochemical steps in the formation of butyric acid and neutral products from sugars is shown in Figure 14.46. In saccharolytic clostridia, such as the well-studied *Clostridium pasteurianum*, 1.5 glucose is converted to 3 pyruvate and 3 NADH via the glycolytic pathway, and each pyruvate is split to yield acetyl-CoA, CO_2 , and Fd_{red} (the “phosphoroclastic reaction” in Figure 14.46). One acetyl-CoA gives rise to acetate and an ATP and the other two are combined and reduced to butyrate to form another ATP. One NADH is reoxidized during the formation of β -hydroxybutyryl-CoA and the other 2 NADH are oxidized in an electron bifurcation reaction (Figure 14.2) that couples the exergonic reduction of crotonyl-CoA to the endergonic reduction of Fd_{ox} . Redox balance is achieved ultimately by a cytoplasmic hydrogenase that uses Fd_{red} to reduce protons to H_2 (Figure 14.43).

The actual fermentation products observed differ between species, and the ratio of these products is influenced by environmental conditions. *Clostridium acetobutylicum* provides a classic example of this pattern. During the early stages of the butyric fermentation, *C. acetobutylicum* produces mostly butyrate and a small amount of acetate, similar to that of *C. pasteurianum*. But the production of butyrate and acetate leads to acid production (Figure 14.46), and acidification of the environment eventually inhibits growth of *C. acetobutylicum*. Hence, as the pH of the medium drops, the organism shifts its fermentation products toward acetone and butanol, “neutral products” that do not lower the pH of the environment. However, if the pH of the medium is kept neutral by buffering, butyric acid production continues, and very little acetone and butanol will be formed because butyrate formation provides a higher yield of ATP (Figure 14.46).

Figure 14.46 The butyric acid and butanol/acetone fermentation. All fermentation products from glucose are shown in bold (dashed lines indicate minor products). Note how the production of acetate and butyrate lead to additional ATP by substrate-level phosphorylation. By contrast, formation of butanol and acetone reduces the ATP yield because the butyryl-CoA to butyrate step is bypassed. The production of butyryl-CoA is an electron bifurcation reaction (Figure 14.2) in which 2 NADH donate electrons to crotonyl-CoA and Fd_{ox}. Fd_{red}, reduced ferredoxin; Fd_{ox}, oxidized ferredoxin.

Interestingly, the production of butanol is a consequence of the production of acetone. For each acetone produced, two NADH cannot be reoxidized in the reduction of crotonyl-CoA. To achieve redox balance, the cell then uses butyrate as an electron acceptor, producing butanol as a fermentation product (Figure 14.46). Although neutral product formation helps *C. acetobutylicum* keep its environment from becoming too acidic, there is an energetic price to pay.

Amino Acid Fermentation by Clostridia and the Stickland Reaction

Some clostridia ferment amino acids. These are the *proteolytic* clostridia, organisms that degrade proteins released from dead organisms. Some of these, such as the animal pathogen *Clostridium tetani*

(tetanus), are strictly proteolytic, while other species are both saccharolytic and proteolytic.

Depending on the species, some proteolytic clostridia ferment individual amino acids, typically glutamate, glycine, alanine, cysteine, histidine, serine, or threonine. The biochemistry behind these fermentations is quite complex, but the metabolic strategy is simple. In virtually all cases, the amino acids are catabolized in such a way as to eventually yield a fatty acid–CoA derivative, typically acetyl (C₂), butyryl (C₄), or caproyl (C₆). From these, ATP is produced by substrate-level phosphorylation (Table 14.5). Other typical products of amino acid fermentation include ammonia (NH₃) and CO₂.

Some clostridia ferment only an amino acid *pair*. In this situation one amino acid functions as the electron donor and is oxidized, whereas the other amino acid is the electron acceptor and is reduced. This *coupled* amino acid fermentation is called a **Stickland reaction**, named for the scientist who discovered it. For example, *Clostridium sporogenes* ferments glycine and alanine, and in this reaction, alanine is the electron donor and glycine is the electron acceptor (Figure 14.47). The products of the Stickland reaction are invariably NH₃, CO₂, and a carboxylic acid with one fewer carbons than the amino acid that was oxidized (Figure 14.47).

Many of the products of amino acid fermentation by clostridia are foul-smelling substances, and the odor that results from putrefaction is mainly a result of clostridial activity. In addition to fatty

Figure 14.47 The Stickland reaction. This example shows the co-catabolism of the amino acids alanine and glycine. The structures of key substrates, intermediates, and products are shown in brackets to allow the chemistry of the reaction to be followed. Note that in the reaction shown, alanine is the electron donor and glycine is the electron acceptor.

acids, other odoriferous compounds produced in proteolytic fermentations include hydrogen sulfide (H_2S), methyl mercaptan (CH_3SH , derived from sulfur-containing amino acids), cadaverine (from lysine), putrescine, and NH_3 . Purines and pyrimidines (◀ Figure 3.34), released from the degradation of nucleic acids, lead to many of the same fermentation products and also yield ATP by substrate-level phosphorylation from the hydrolysis of fatty acid–CoA derivatives (Table 14.5) produced in their respective fermentative pathways.

Energy-Converting Hydrogenases

Pyrococcus furiosus is a hyperthermophilic species of *Archaea* that grows optimally at 100°C (▶ Section 17.4) by fermenting sugars and small peptides. It uses the early reactions of glycolysis (◀ Figure 3.11) to convert glucose into two glyceraldehyde 3-phosphate, but then produces two molecules of 3-phosphoglycerate instead of two 1,3-bisphosphoglycerate, as normally occurs in glycolysis (Figure 14.48). In so doing, *P. furiosus* forgoes the ability to make ATP from the energy-rich phosphate bonds in 1,3-bisphosphoglycerate and instead forms Fd_{red} . Additional ATP and Fd_{red} are formed in the subsequent conversion of pyruvate to acetate (Figure 14.48). *P. furiosus* is then able to use an energy-converting hydrogenase (Figure 14.43) to reoxidize Fd_{red} and achieve redox balance, but this hydrogenase also has the ability to translocate one Na^+ across the

membrane for each proton reduced. A Na^+ -linked ATPase then uses the sodium motive force to synthesize ATP (Figure 14.48).

Ultimately, *P. furiosus* obtains two-thirds (4 ATP) of its energy from substrate-level phosphorylation and one-third (2 ATP) from oxidative phosphorylation driven by proton respiration linked to a Na^+ pump. By using this strategy, *P. furiosus* yields a net of 4 ATP per glucose (Figure 14.48), whereas lactic acid bacteria only obtain 2 ATP per glucose (Figure 14.44). Like *P. furiosus*, many obligately anaerobic fermentative organisms use energy-converting hydrogenases to achieve redox balance and thereby conserve some energy in the form of a proton or sodium motive force. Is this respiration or is it fermentation? Some metabolic reactions are difficult to classify, but the majority of energy is conserved in substrate-level phosphorylation, a trait that is a defining feature of fermentative metabolisms.

Is fermentation the “end of the line” in terms of the energy extracted from the initial substrate? Not quite, as we see in the final three sections of this part of the chapter.

Check Your Understanding

- Why does *Clostridium acetobutylicum* need to produce butanol as a fermentation product when it is producing acetone?
- What type of substrates are fermented by saccharolytic clostridia? By proteolytic clostridia?
- What aspects of metabolism in *Pyrococcus furiosus* are unusual for a fermentative organism?

Figure 14.48 Modified glycolysis and proton reduction in anaerobic respiration in the hyperthermophile *Pyrococcus furiosus*. Hydrogen (H_2) production is linked to H^+ pumping by an energy-converting hydrogenase (see Figure 14.43) that receives electrons from reduced ferredoxin (Fd_{red}). Compare this figure with classical glycolysis in Figure 3.11. G-3-P, glyceraldehyde 3-phosphate; 3-PGA, 3-phosphoglycerate; PEP, phosphoenolpyruvate.

14.20 Secondary Fermentations

In addition to classifying fermentations by the substrate fermented or product(s) produced (Section 14.18 and Table 14.6), fermentations can be classified as *primary* or *secondary*. Primary fermentations are carried out by organisms that break down and ferment various polymers and monomers of carbohydrate, protein, and fat to reduced products including acids and alcohols as well as H_2 and CO_2 . **Secondary fermentations** use these fermentation products as substrates for additional fermentation reactions whose products are mainly volatile fatty acids (such as butyrate, propionate, and acetate), H_2 , and CO_2 .

Propionic Acid Fermentation

The gram-positive bacterium *Propionibacterium* and some related bacteria produce *propionic acid* as a major fermentation product from either glucose or lactate. Lactate, a fermentation product of the lactic acid bacteria (Section 14.18), is probably the major substrate for propionic acid bacteria in nature, where these two groups live in close association. *Propionibacterium* is an important agent in the ripening of Emmental (Swiss) cheese, which gets its unique bitter and nutty taste from the propionic and acetic acids produced; the CO_2 produced during the fermentation forms bubbles that leave the characteristic holes (eyes) in the cheese.

Figure 14.49 shows the reactions leading from lactate to propionate. When glucose is the starting substrate, it is first catabolized to pyruvate by the glycolytic pathway. Then pyruvate, produced either from glucose or from the oxidation of lactate, is converted to acetate plus CO_2 or carboxylated to form methylmalonyl-CoA; the latter is converted into oxaloacetate and, eventually, propionyl-CoA

Figure 14.49 The propionic acid fermentation of *Propionibacterium*. Products are shown in bold. The four NADH made from the oxidation of three lactate are reoxidized in the reduction of oxaloacetate and fumarate, and the CoA group from propionyl-CoA is exchanged with succinate during the formation of propionate.

(Figure 14.49). Propionyl-CoA reacts with succinate in a step catalyzed by the enzyme CoA transferase, producing succinyl-CoA and propionate. This results in a lost opportunity for ATP production from propionyl-CoA (Table 14.5) but avoids the energetic costs of having to activate succinate with ATP to form succinyl-CoA. The succinyl-CoA is then isomerized to methylmalonyl-CoA and the cycle is complete when propionate is formed and CO₂ regenerated (Figure 14.49).

NADH is oxidized in the steps between oxaloacetate and succinate. The reduction of fumarate to succinate (Figure 14.49) is linked to electron transport reactions (Section 14.13) and the formation of a proton motive force; this yields one ATP by oxidative phosphorylation. The propionate pathway also converts some pyruvate to acetate plus CO₂, which allows for additional ATP to be made by substrate-level phosphorylation because this reaction proceeds through the energy-rich intermediate acetyl-CoA (Table 14.5 and Figure 14.49). Thus, in the propionate fermentation, both substrate-level and oxidative phosphorylation occur.

Propionate is also formed in the fermentation of succinate by the bacterium *Propionigenium*, but by a completely different mechanism than that described here for *Propionibacterium*. *Propionigenium*, to be considered in Section 14.21, is phylogenetically and ecologically unrelated to *Propionibacterium*, but aspects of its energy metabolism are of considerable interest from the standpoint of metabolic diversity and the energetic limits to life.

Clostridium kluyveri Fermentation

Clostridium kluyveri ferments two substrates: ethanol plus acetate. This is an unusual secondary fermentation in that ethanol is the electron

donor and acetate is the electron acceptor, and butyrate, caproate, and H₂ are the products. The overall reaction in the caproate/butyrate fermentation is shown in Table 14.6 and begins with 6 ethanol and 3 acetate as substrates. The oxidation of 6 ethanol to 6 acetyl-CoA results in the production of 12 NADH. Then, using the same reactions we saw in butyric acid fermentation (Figure 14.46), one acetyl-CoA is used to produce acetate and ATP by substrate-level phosphorylation. Next, the 3 acetate molecules are activated by adding CoA, giving a total of 8 acetyl-CoA. These molecules are used in the butyric acid pathway to accept electrons from the 12 NADH generated earlier, thereby producing 4 butyryl-CoA (as in Figure 14.46).

As in the butyric acid fermentation, the production of 4 butyryl-CoA is mediated by an electron bifurcation reaction (Figure 14.2) producing 4 Fd_{red}, two of which give rise to H₂. However, *C. kluyveri*, unlike *C. pasteurianum*, has a membrane-bound NAD⁺-ferredoxin oxidoreductase (RnfA–G) that uses the exergonic reduction of NAD⁺ by Fd_{red} to pump protons across the membrane, thereby generating a pmf (Rnf is also found in acetogens, see Figure 14.34). The two remaining Fd_{red} are used by the Rnf enzyme complex to produce 2 NADH and to pump 4 H⁺ across the membrane, enough to make one ATP by oxidative phosphorylation. Finally, we are left with 2 NADH, 1 acetyl-CoA, and 4 butyryl-CoA. The CoA are transferred from 3 of the butyryl-CoA to activate the 3 acetate at the beginning of the pathway, producing 3 butyrate. Lastly, the 2 remaining NADH are used to make caproate from the final butyryl-CoA and the acetate produced earlier in the pathway, yielding the final fermentation products: 3 butyrate, 1 caproate, and 2 H₂.

We can see several themes at work in the fermentation of *C. kluyveri*. First, we see the modularity of metabolism in the way that *C. kluyveri* has adapted the butyric acid pathway to perform a butyrate-based fermentation that is distinct from that of *C. pasteurianum*. Second, we can see how metabolic intermediates are often recycled and reused within fermentative pathways to achieve redox balance. Third, we see that organisms can enhance their metabolic efficiency by using mechanisms such as electron bifurcation and using reduced ferredoxin as electron donor to generate a proton motive force with protons or NAD⁺ as electron acceptor.

In the final two sections of this part of the chapter, we will see more examples of microbes that employ innovative strategies for living at the thermodynamic edge of life.

Check Your Understanding

- What aspects of energy conservation are shared by both *Propionibacterium* and *Clostridium kluyveri*?
- What is meant by the terms primary and secondary fermentation?
- How is the Rnf enzyme complex of *Clostridium kluyveri* similar to the energy-converting hydrogenase of *Pyrococcus furiosus*? How are they different?

14.21 Fermentations That Lack Substrate-Level Phosphorylation

Certain fermentations yield insufficient energy to synthesize ATP by substrate-level phosphorylation (that is, less than -31.8 kJ , Table 14.5), yet still support anaerobic growth without external

electron acceptors. In these cases, catabolism of the compound is linked to ion pumps that establish an ion gradient across the cytoplasmic membrane. Examples of these include the fermentation of succinate by *Propionigenium modestum* and the fermentation of oxalate by *Oxalobacter formigenes*.

Propionigenium modestum

Propionigenium modestum was first isolated in anoxic enrichment cultures lacking electron acceptors and fed succinate as an electron donor. *Propionigenium* inhabits marine and freshwater sediments and can also be isolated from the human oral cavity. The organism is a gram-negative short rod and, phylogenetically, is a species of *Fusobacteria*. During studies of the physiology of *P. modestum*, it was shown to require sodium chloride (NaCl) for growth and to catabolize succinate under strictly anoxic conditions:

This is a disproportionation reaction (Section 14.12) in which part of the succinate molecule is reduced to propionate and the other part is oxidized to CO_2 (Figure 14.50a). Energy is conserved by an unusual enzyme that decarboxylates (S)-methylmalonyl-CoA and adds a proton to it to produce propionyl-CoA. The enzyme uses the energy released from this decarboxylation reaction to translocate two Na^+ across the membrane. Energy is then conserved using a Na^+ -linked ATPase as we have seen for acetogens (Section 14.14), methanogens (Section 14.15), and *Pyrococcus* (Section 14.19).

In a related decarboxylation reaction, the bacterium *Malonomonas rubra* decarboxylates the C_3 dicarboxylic acid malonate, forming

acetate plus CO_2 . As for *Propionigenium*, energy metabolism in *Malonomonas* is linked to Na^+ and a sodium-driven ATPase. But the free energy available from malonate fermentation by *Malonomonas* (-17.4 kJ) is even less than that of succinate fermentation by *P. modestum*. *Sporomusa*, an endospore-forming bacterium and also an acetogen (Section 14.14), is also capable of fermenting malonate, as are a few other anaerobic *Bacteria*.

Oxalobacter formigenes

Oxalobacter formigenes is a bacterium present in the intestinal tract of animals, including humans. It performs a disproportionation reaction using the C_2 dicarboxylic acid oxalate, reducing one part of the molecule to formate and oxidizing the other part to CO_2 (Figure 14.50b). Oxalate degradation by *O. formigenes* is thought to be important in the human colon for preventing the accumulation of oxalate, a substance that can form calcium oxalate kidney stones. *O. formigenes* is a gram-negative strict anaerobe that carries out the following reaction:

As in the catabolism of succinate by *P. modestum*, insufficient energy is available from this reaction to drive ATP synthesis by substrate-level phosphorylation (Table 14.5). In addition, remarkably, the organism does not have a mechanism for pumping ions out of the cell. Energy is conserved because protons are consumed in the cytoplasm during the oxidation of oxalate and production of formate. Looked at another way, a divalent molecule (oxalate) enters the cell while a univalent molecule (formate) is excreted, and this

Figure 14.50 The unique fermentations of succinate and oxalate. (a) Succinate fermentation by *Propionigenium modestum*. Sodium export is linked to the energy released by succinate decarboxylation, and a sodium-translocating ATPase produces ATP. (b) Oxalate fermentation by *Oxalobacter formigenes*. Oxalate import and formate export by a formate-oxalate antiporter (◀ Figure 2.6) consume cytoplasmic protons. ATP synthesis is linked to a proton-driven ATPase. All substrates and products of the fermentation are shown in black bold.

contributes to the energy of the electrochemical gradient. Together, these forces allow for the formation of a proton motive force sufficient to drive ATP synthesis (Figure 14.50b).

What Can Be Learned from the Decarboxylations of Succinate and Oxalate?

The unique aspect of decarboxylation-type fermentations is that ATP is made without substrate-level phosphorylation or electron transport reactions. In both cases, ATP synthesis is driven by a disproportionation reaction in which a redox reaction is used to generate an ion gradient directly, either by consuming protons, as in *Oxalobacter*, or by fueling an ion pump, as in *Propionigenium*. We also see this trend reflected in energy-converting hydrogenases (as in some sulfate reducers, acetogens, methanogens, and fermenters) and in the Rnf enzyme complex (as in some acetogens and fermenters), which both couple a redox reaction directly to an ion-pumping mechanism. All of these mechanisms offer an important lesson in microbial bioenergetics: ATP synthesis from reactions that yield less than -31.8 kJ/mol is still possible if the reaction can be coupled to an ion pump.

At a minimum, then, an energy-conserving reaction must yield sufficient free energy to pump at least one ion. This energy requirement is estimated to be near -12 kJ. Reactions that release less free energy than this should not be able to drive ion pumps and should therefore not be potential energy-conserving reactions. However, as we will see in the next section, bacteria are known that push this theoretical limit even lower, and their energetics, consequently, are still incompletely understood. These are the syntrophs, bacteria living on the energetic margin of existence.

Check Your Understanding

- Why does *Propionigenium modestum* require sodium for growth?
- Of what benefit is the organism *Oxalobacter* to human health?
- How can a fermentation that yields insufficient free energy to make an ATP still support growth?

14.22 Syntrophy

There are many examples in microbiology of **syntrophy**, a situation in which two different microbes cooperate to perform a metabolic reaction that neither can accomplish alone. Most syntrophic reactions are secondary fermentations in which organisms ferment the fermentation products of other anaerobes. We will see in Chapter 21 how syntrophy is often a key step in anaerobic food webs and in the anaerobic metabolisms that lead to the production of methane in nature. Here we consider the microbiology and energetic aspects of syntrophy.

Interspecies Electron Transfer

Many organic compounds can be degraded syntrophically, including even aromatic and aliphatic hydrocarbons. But the major compounds of interest in syntrophic environments are fatty acids and alcohols. The heart of syntrophic reactions is *interspecies electron transfer*, defined as a relationship between two organisms in which one species serves as the electron acceptor for another species that

is the electron donor. This relationship can be direct (*direct interspecies electron transfer*, DIET), mediated by either direct contact between the cells or by direct electrical connections established by using nanowires (Section 14.13). Alternatively, the relationship can be mediated (*mediated interspecies electron transfer*, MIET) by metabolic products that are exchanged by diffusion between cells. H_2 mediates many syntrophic partnerships since many fermentative organisms readily produce it and many respiratory organisms readily consume it. We will encounter examples of DIET in Chapter 23. Here we consider only how the exchange of metabolic products allows both syntrophic partners to thrive.

As an example of syntrophy, consider the fermentation of ethanol to acetate plus H_2 by the syntroph *Pelotomaculum* coupled to the production of methane (Figure 14.51). The syntroph carries out a reaction whose standard free-energy change ($\Delta G^{\circ'}$) is positive. Hence, in pure culture, the organism will not grow. However, the H_2 produced by *Pelotomaculum* can be used as an electron donor by a methanogen to produce methane, an exergonic reaction. When the two reactions are summed, the overall reaction is exergonic (Figure 14.51a), and when *Pelotomaculum* and a methanogen are cultured together (cocultured), both organisms grow.

A second example of syntrophy is the oxidation of a fatty acid such as butyrate to acetate plus H_2 by the fatty acid-oxidizing bacterium *Syntrophomonas* (Figure 14.52a). *Syntrophomonas* oxidizes butyrate by reversing most steps in the butyric acid fermentation pathway (see Figure 14.46). However, the electron-bifurcating enzyme of butyric acid fermentation is replaced by an enzyme that oxidizes butyryl-CoA to produce NADH (Figure 14.52a). The two NADH produced in butyrate oxidation are oxidized in an electron

Coupled reaction in coculture of syntroph and methanogen:

(a) Reactions

(b) Overview of syntrophic transfer of H_2

Figure 14.51 Syntrophy: Interspecies H_2 transfer. Shown is the fermentation of ethanol to methane and acetate by syntrophic association of an ethanol-oxidizing syntroph and a H_2 -consuming partner (in this case, a methanogen). (a) Reactions involved. The two organisms share the energy released in the coupled reaction. (b) Overview of the syntrophic transfer of H_2 .

(a) Syntrophic culture

(b) Pure culture

Figure 14.52 Energetics of growth of *Syntrophomonas* in syntrophic culture and in pure culture. (a) In syntrophic culture, growth requires a H_2 -consuming organism, such as a methanogen. H_2 production is driven by reverse electron transport because the E_0' values of the NADH couple are more electropositive than that of $2 H^+/H_2$. (b) In pure culture, energy conservation is linked to anaerobic respiration with crotonate reduction to butyrate. Inset: photomicrograph of cells of a fatty acid-degrading syntrophic bacterium (red) in association with a methanogen (green-yellow).

bifurcation reaction to reduce Fd_{ox} and menaquinone (Q). The Fd_{red} is then used by a cytoplasmic hydrogenase to produce one H_2 , and the QH_2 is used in a membrane-associated endergonic reaction to reduce $2 H^+$ to H_2 . The free-energy change of this overall reaction is even more unfavorable than that of ethanol oxidation and in pure culture *Syntrophomonas* will obviously not grow on butyrate (Figure 14.52a). However, as with ethanol fermentation by *Pelotomaculum*, if the H_2 produced by *Syntrophomonas* is consumed by a partner organism, *Syntrophomonas* will grow on butyrate in coculture with the H_2 -consuming partner. How does this occur?

Energetics of H_2 Transfer

In a syntrophic relationship, the removal of H_2 by a partner organism shifts the equilibrium of the entire reaction and pulls it in the

direction of product formation; this can greatly affect the energetics of the reaction. Recall from our consideration of the principles of free energy (Section 3.3) that the concentration of reactants and products in a reaction can have a major effect on the reaction's energetics. Said another way, the $\Delta G^{0'}$ of a reaction calculated under *standard* conditions may well differ from the ΔG of the reaction calculated under *actual* conditions (Figure 3.7). At very low H_2 concentration, the energetics of oxidizing butyrate (or ethanol, or other fatty acids) to acetate plus H_2 become exergonic. For example, if a partner organism keeps the concentration of H_2 extremely low, the oxidation of butyrate by *Syntrophomonas* yields -18 kJ/mol (Figure 14.52a).

While H_2 transfer is characteristic of many syntrophic associations, particularly those associated with fermentation, it is also possible to have syntrophic associations in which *only electrons* are transferred. In direct electron transfer, such as the anoxic consumption of CH_4 by the ANME-sulfate reducer consortium (Section 14.16 and Figure 14.41), we learned that some respiratory syntrophs can use electrically conductive proteins (large multiheme cytochromes and “nanowires”) to transfer electrons directly between cells separated by significant distances. In such syntrophic reactions, direct electron transfer does not depend on diffusion rates or H_2 concentrations because the electron transfer results from a direct connection between two cells.

Ecology of Syntrophs

Ecologically, syntrophic bacteria are key links in the anoxic steps of the carbon cycle (Section 21.2). Syntrophs consume highly reduced fermentation products and release a key product, H_2 , for anaerobic respirations. Without syntrophs, a bottleneck would develop in anoxic environments in which electron acceptors (other than CO_2) were limiting. By contrast, when conditions are oxic or alternative electron acceptors are abundant, syntrophic relationships are unnecessary. For example, if O_2 or NO_3^- is available as an electron acceptor, the energetics of the respiration of a fatty acid or an alcohol is so favorable that syntrophic relationships are unnecessary. Thus, syntrophy is characteristic of anoxic catabolisms in which primarily methanogenesis or acetogenesis are the terminal processes in the ecosystem. Methanogenesis is a major process in anoxic wastewater biodegradation, and microbiological studies of sludge granules that form in such systems have shown the close physical relationship that develops between H_2 producer and H_2 consumer in such habitats (Figure 14.52a inset).

The final part of this chapter, Part VII, considers the catabolism of a specific class of substrates: hydrocarbons. These electron donors, common in nature, can be degraded both aerobically and anaerobically, and once again, metabolic diversity is on display.

Check Your Understanding

- Give an example of interspecies H_2 transfer. How is it that both organisms benefit from this process?
- Could *Syntrophomonas* grow in a syntrophic association with a butyric acid fermenter like *Clostridium pasteurianum*?
- How does *Syntrophomonas* produce H_2 , and what makes this possible?

VII • Hydrocarbon Metabolism

Hydrocarbons are organic compounds that are devoid of oxygen and can be catabolized both aerobically and anaerobically. Hydrocarbon catabolism requires oxygen, and anaerobically, a series of unique reactions solves this biochemical conundrum.

Hydrocarbons, molecules that contain only carbon and hydrogen atoms, are widely used by microbes as electron donors, and we wrap up our coverage of metabolic diversity with a consideration of this process. Unlike methane, hydrocarbons containing two or more carbons typically have to be oxygenated before they can be catabolized. We first consider the aerobic catabolism of aliphatic and aromatic hydrocarbons, where this oxygenation involves O_2 . We then proceed with a consideration of anoxic hydrocarbon metabolism, a situation where oxygenation of the hydrocarbon is still necessary, but where O_2 obviously plays no role.

14.23 Aerobic Hydrocarbon Metabolism

We previously discussed the role of molecular oxygen (O_2) as an *electron acceptor* in energy-generating reactions. By contrast, O_2 also plays an important role as a *reactant* in the catabolism of hydrocarbons, and oxygenase enzymes are key players in the process.

Oxygenases and Aliphatic Hydrocarbon Oxidation

Oxygenases are enzymes that catalyze the incorporation of O_2 into organic compounds and in some cases, inorganic compounds (Section 14.9). There are two classes of oxygenases: *dioxygenases*, which catalyze the incorporation of *both atoms* of O_2 into the molecule, and *monooxygenases*, which catalyze the incorporation of *only one* of the two oxygen atoms of O_2 into an organic compound with the second atom of O_2 being reduced to H_2O . For most monooxygenases, the required electron donor is NADH or NADPH.

In the initial oxidation step of a saturated aliphatic (straight-chain) hydrocarbon, one of the atoms of O_2 is incorporated, typically at a terminal carbon atom. This reaction is catalyzed by a monooxygenase, and a typical reaction sequence is shown in **Figure 14.53a**. The end product of the reaction sequence is a fatty acid of the same length as the original hydrocarbon. The fatty acid is then oxidized by *beta-oxidation*, a series of reactions in which two carbons of the fatty acid are split off at a time (Figure 14.53b). During beta-oxidation, NADH is formed and is oxidized in the electron transport chain for energy conservation purposes (◀ Figure 3.19). A single round of beta-oxidation releases acetyl-CoA plus a new fatty acid that is two carbon atoms shorter than the original fatty acid. The process of beta-oxidation is then repeated, and another acetyl-CoA molecule is released. The acetyl-CoA formed by beta-oxidation is either oxidized through the citric acid cycle (◀ Figure 3.12) or used

Figure 14.53 Monooxygenase activity and beta-oxidation. (a) Steps in the oxidation of an aliphatic hydrocarbon, the first of which is catalyzed by a monooxygenase. (b) Fatty acid oxidation by beta-oxidation leads to the successive formation of acetyl-CoA.

to make new cell material. With the exception of how the hydrocarbon is oxygenated, much of the biochemistry of anoxic hydrocarbon catabolism is the same as that shown for aerobic catabolism (Figure 14.53), with beta-oxidation reactions being of prime importance in both cases.

Aromatic Hydrocarbon Oxidation

Many aromatic (ringed) hydrocarbons can also be used as electron donors aerobically by microorganisms. The metabolism of these compounds, some of which contain multiple rings, such as naphthalene or biphenyls, typically has as its initial stage the formation of catechol or a structurally related compound via catalysis by oxygenase enzymes, as shown in Figure 14.54. Once catechol is formed it can be cleaved and further degraded into compounds that can enter the citric acid cycle, such as succinate, acetyl-CoA, and pyruvate.

Several steps in the aerobic catabolism of aromatic hydrocarbons require oxygenases. Figure 14.54a–c shows four different oxygenase-catalyzed reactions, one using a monooxygenase, two using a ring-cleaving dioxygenase, and one (toluene dioxygenase) using a ring-hydroxylating mechanism. As in aerobic aliphatic hydrocarbon catabolism (Figure 14.53), aromatic compounds, whether single- or multi-ringed, are typically oxidized completely to CO_2 , with electrons entering an electron transport chain or used to make new cell material.

Figure 14.54 Roles of oxygenases in catabolism of aromatic compounds. Monooxygenases introduce one atom of oxygen from O_2 into a substrate, whereas dioxygenases introduce both atoms of oxygen. (a) Hydroxylation of benzene to catechol by a monooxygenase in which NADH is an electron donor. (b) Cleavage of catechol to *cis,cis*-muconate by an intradiol ring-cleavage dioxygenase. (c) The activities of a ring-hydroxylating dioxygenase and an extradiol ring-cleavage dioxygenase in the degradation of toluene. The oxygen atoms that each enzyme introduces are distinguished by different colors. Compare aerobic toluene catabolism to anoxic toluene catabolism shown in Figure 14.55b.

Check Your Understanding

- How do monooxygenases differ in function from dioxygenases?
- What is the final product of catabolism of a hydrocarbon?
- What is meant by the term beta-oxidation?

14.24 Anaerobic Hydrocarbon Metabolism

Although aerobic hydrocarbon oxidation is a major process in nature, anaerobic hydrocarbon oxidation linked to the reduction of nitrate, sulfate, or ferric iron as electron acceptors in anaerobic respirations (Sections 14.11–14.13) is also possible. And, as for the aerobic process, both aliphatic and aromatic hydrocarbons can be degraded anaerobically.

Aliphatic Hydrocarbons

Aliphatic hydrocarbons are substrates for denitrifying and sulfate-reducing bacteria. Saturated aliphatic hydrocarbons as long as C_{20} support growth, although shorter-chain hydrocarbons are more soluble and therefore more readily catabolized. The mechanism of anoxic hydrocarbon degradation has been well studied for hexane (C_6H_{14}) metabolism in denitrifying bacteria, organisms that use NO_3^- as an electron acceptor (► Section 15.10). However, the mechanism appears to be the same for the anoxic catabolism of longer-chain hydrocarbons and for anoxic hydrocarbon oxidation linked to other electron acceptors, and so we focus on the hexane/nitrate system here.

In anoxic hexane metabolism, hexane is modified on carbon atom 2 by attachment of a molecule of fumarate, a C_4 intermediate of the citric acid cycle (◀ Figure 3.12), forming the compound 1-methylpentylsuccinate (Figure 14.55a). The enzymatic addition of fumarate to hexane oxygenates the hydrocarbon without the need for O_2 and allows the molecule to be further catabolized anaerobically.

Following the addition of coenzyme A, a series of reactions occurs that includes beta-oxidation (Figure 14.53b) and regeneration of fumarate (Figure 14.55a). The electrons released during beta-oxidation generate a proton motive force and are consumed in nitrate or sulfate reduction (Sections 14.11 and 14.12, respectively).

Aromatic Hydrocarbons

Aromatic hydrocarbons can also be degraded anaerobically through anaerobic respirations. For anoxic catabolism of the aromatic hydrocarbon toluene, oxygen needs to be added and this also occurs by the addition of fumarate (Figure 14.55b). The reaction series eventually yields benzoyl-CoA, which is further degraded by ring reduction (see Figure 14.56). Benzene

Figure 14.55 Anoxic catabolism of two hydrocarbons. (a) In anoxic catabolism of the aliphatic hydrocarbon hexane, the addition of fumarate provides the oxygen atoms necessary to form a fatty acid derivative that can be catabolized by beta-oxidation (see Figure 14.53b) to yield acetyl-CoA. Electrons (H) generated from hexane catabolism are used to reduce sulfate or nitrate in anaerobic respirations. (b) Fumarate addition during the anoxic catabolism of the aromatic hydrocarbon toluene forms benzylsuccinate.

(C_6H_6) can also be catabolized anaerobically, likely by a similar mechanism. Multi-ringed aromatic hydrocarbons such as naphthalene ($C_{10}H_8$) can be degraded by certain sulfate-reducing and denitrifying bacteria. But in contrast to other hydrocarbons, the oxygenation of multi-ringed hydrocarbons occurs by the addition of CO_2 to the ring to form a carboxylic acid derivative rather than by fumarate addition. However, this carboxylation reaction serves the same biochemical purpose as oxygenase reactions (Figures 14.53a and 14.54) or the addition of fumarate (Figure 14.55); an O atom becomes part of the hydrocarbon and facilitates its catabolism.

Many bacteria can catabolize certain aromatic hydrocarbons anaerobically, including even fermentative and phototrophic purple bacteria. However, except for toluene, only aromatic compounds that already contain an O atom are degraded, typically by a

common mechanism. In contrast to aerobic catabolism that occurs by way of ring *oxidation* (Figure 14.54), anaerobic catabolism proceeds by ring *reduction*. The anaerobic degradation of aromatic hydrocarbons is often facilitated by their conversion into benzoate followed by aromatic ring cleavage and benzoate catabolism performed by the *benzoyl-CoA pathway* (Figure 14.56). Benzoate catabolism in this pathway begins by forming the coenzyme A derivative followed by ring cleavage to yield fatty or dicarboxylic acids (Figure 14.56) that can be further catabolized to intermediates of the citric acid cycle (◀ Figure 3.12).

As we reach the end of our survey of metabolic diversity, we need not keep in mind all of the metabolic details, for they are numerous and formidable, but instead, we need to see the “metabolic big picture” formed by the major themes of this chapter: the modularity of

Figure 14.56 Anoxic degradation of benzoate by the benzoyl-CoA pathway. This pathway operates in the purple phototrophic bacterium *Rhodospseudomonas palustris* and many other facultative bacteria, both phototrophic and chemotrophic. Note that all intermediates of the pathway are bound to coenzyme A. The acetate produced is further catabolized in the citric acid cycle.

metabolism, and the key processes of phototrophy, chemolithotrophy, and autotrophy, respirations by electron donor or electron acceptor, C₁ metabolisms, fermentations, and hydrocarbon metabolism. These overarching principles will guide us through the next four chapters where our focus will be the diversity of the microbes themselves rather than their metabolisms. Chapters 15–17 in particular will cover many of the *Bacteria* and *Archaea* whose metabolisms we have described here, and we will witness there the many

cases in which metabolic diversity and prokaryotic diversity are inextricably linked.

Check Your Understanding

- What is the benzoyl-CoA pathway, and how might it participate in the anaerobic degradation of toluene?
- How is hexane oxygenated during anoxic catabolism?

CHAPTER REVIEW

I • Introduction to Metabolic Diversity

- 14.1** All cells must conserve energy, have a source of reducing power, and achieve redox balance in their metabolism. Energy is conserved through substrate-level phosphorylation, oxidative phosphorylation, or photophosphorylation. Reducing power is supplied by electron donors or must be generated in endergonic reactions. Redox balance is achieved by using terminal electron acceptors (in respiration) or fermentation products (including H₂) to export electrons from the cell.

Q What are reverse electron transport and electron bifurcation, and what role do they play in generating reducing power and achieving redox balance?

- 14.2** Autotrophy is supported in most phototrophic and chemolithotrophic bacteria by the Calvin cycle, in which the enzyme RuBisCO plays a key role. The reverse citric acid and hydroxypropionate cycles are autotrophic pathways in green sulfur and green nonsulfur bacteria, respectively.

Q What is a carboxysome, and what is its role in CO₂ fixation? Plants do not have carboxysomes; how might this affect the efficiency with which they fix CO₂?

II • Phototrophy

- 14.3** In photosynthesis, ATP is generated from light and then consumed in the reduction of CO₂. Two forms of photosynthesis are known: oxygenic, where O₂ is produced

(for example, in cyanobacteria), and anoxygenic, where it is not (for example, in purple and green bacteria). Photosynthetic reaction centers and photosynthetic pigments reside in membranes where the light reactions of photosynthesis are carried out.

Q What are the functions of light-harvesting and reaction center chlorophylls?

- 14.4** Accessory pigments including carotenoids and phycobilins absorb light and transfer the energy to reaction center chlorophyll, thus broadening the wavelengths of light usable in photosynthesis. Carotenoids also play an important photoprotective role in preventing photooxidative damage to cells.

Q What accessory pigments are present in phototrophs, and what are their functions?

- 14.5** In anoxygenic phototrophs, electron transport reactions in photosynthetic membranes are driven by the photosynthetic reaction center, forming a proton motive force and ATP.

Q Why is reverse electron transport necessary in purple sulfur bacteria but not in green sulfur bacteria?

- 14.6** In oxygenic photosynthesis, H₂O donates electrons to drive CO₂ fixation, and O₂ is a by-product. There are two separate but interconnected photosystems in oxygenic phototrophs, PSI and PSII, whereas anoxygenic phototrophs contain a single photosystem.

Q How does the reduction potential (E_0') of chlorophyll *a* in PSI and PSII differ? Why must the reduction potential of PSII chlorophyll *a* be so highly electropositive?

III • Respiratory Processes Defined by Electron Donor

- 14.7** Reduced sulfur compounds such as H_2S , $\text{S}_2\text{O}_3^{2-}$, and S^0 are electron donors for energy conservation in sulfur chemolithotrophs. Electrons from these substances enter electron transport chains, yielding a proton motive force. Sulfur chemolithotrophs are also autotrophs and fix CO_2 by the Calvin cycle.

Q Compare and contrast the utilization of H_2S by a purple phototrophic bacterium and by a colorless sulfur bacterium such as *Beggiatoa*. What role does H_2S play in the metabolism of each organism?

- 14.8** Chemolithotrophic iron bacteria oxidize Fe^{2+} as an electron donor. Most iron bacteria grow at acidic pH and are often associated with acidic pollution from mineral and coal mining. A few chemolithotrophic and phototrophic bacteria can oxidize Fe^{2+} to Fe^{3+} anaerobically.

Q Why do most iron-oxidizing bacteria grow at an acidic pH?

- 14.9** The ammonia-oxidizing *Bacteria* and *Archaea* produce nitrite from ammonia, which is oxidized by nitrite-oxidizing *Bacteria* to nitrate.

Q Are there any types of *Bacteria* or *Archaea* that are able to oxidize ammonia to nitrate?

- 14.10** Anoxic ammonia oxidation (anammox) consumes both ammonia and nitrite, forming N_2 . The anammox reaction occurs within a membrane-enclosed compartment called the anammoxosome.

Q Contrast classical nitrification with anammox in terms of oxygen requirements, organisms involved, and the need for monooxygenases.

IV • Respiratory Processes Defined by Electron Acceptor

- 14.11** Nitrate is a common electron acceptor in anaerobic respiration. Nitrate reduction is catalyzed by the enzyme nitrate reductase, reducing NO_3^- to NO_2^- . Denitrification is an anaerobic respiratory process through which NO_3^- is reduced to gaseous nitrogen compounds including NO , N_2O , or N_2 .

Q Why is it that denitrifiers that reduce NO_3^- to N_2 can still release significant amounts of N_2O ?

- 14.12** Sulfate-reducing bacteria are obligately anaerobic bacteria that reduce SO_4^{2-} to H_2S in a process in which SO_4^{2-} must first be activated to adenosine phosphosulfate (APS). Some sulfur-reducing organisms can reduce S^0 but not SO_4^{2-} to H_2S .

Q Why is the enzyme hydrogenase useful to *Desulfovibrio* even when it is not grown on H_2 as electron donor?

- 14.13** Iron-reducing bacteria can use nanowires to reduce insoluble electron acceptors on the outside of the cell. Many different electron-accepting respiratory reactions are possible

including the reduction of various metals and metalloids, fumarate and other organic compounds, and various chlorinated compounds.

Q In what way might bacteria alter the toxicity of groundwater contaminated with arsenic, chromium, or even uranium?

V • One-Carbon (C_1) Metabolism

- 14.14** Acetogens are strict anaerobes that reduce CO_2 to acetate, usually with H_2 as electron donor. The mechanism of acetate formation is the reductive acetyl-CoA pathway, a pathway widely distributed in obligate anaerobes for either autotrophic purposes or acetate oxidation.

Q Describe the mechanism of energy conservation for acetogens growing on $\text{H}_2 + \text{CO}_2$.

- 14.15** Methanogenesis is the production of CH_4 from $\text{CO}_2 + \text{H}_2$ or from acetate or methanol by strictly anaerobic methanogenic *Archaea*. Several unique coenzymes are required for methanogenesis, and energy conservation is linked to either a proton or sodium motive force.

Q Why is it that methanogens that lack cytochromes are unable to grow on methanol?

- 14.16** Methanotrophy is the use of CH_4 as both carbon source and electron donor. Aerobic methanotrophs use the enzyme methane monooxygenase and oxidize CH_4 to formaldehyde, which is then assimilated by the cell through one of two pathways. Methane can also be oxidized anaerobically by diverse organisms through syntrophic partnerships or by generating O_2 as a catalyst for CH_4 oxidation.

Q Which pathway for C_1 assimilation found in aerobic methanotrophs is most energetically efficient and why? In what ways does *Methylobacillus oxyfera* resemble denitrifiers and aerobic methanotrophs, and in what ways does it differ?

VI • Fermentation

- 14.17** In the absence of external electron acceptors, organic compounds can be catabolized anaerobically only by fermentation. In fermentation, most ATP is typically formed by substrate-level phosphorylation. Redox balance is achieved by the excretion of fermentation products.

Q Define the term substrate-level phosphorylation: How does it differ from oxidative phosphorylation? What compound(s) do fermentative bacteria need to synthesize in order to make ATP by substrate-level phosphorylation?

- 14.18** The lactic acid fermentation is carried out by homofermentative species, where lactate is the sole product, and heterofermentative species, where lactate, ethanol, and CO_2 are produced. The mixed-acid fermentation typical of enteric bacteria yields various acids plus neutral products (ethanol, butanediol), depending on the organism.

Q What are the major fermentation products of *Lactobacillus* and *Escherichia*?

- 14.19** Clostridia ferment sugars, amino acids, and other organic compounds, with butyric and acetic acids and H_2 being major products. Butyrate production allows for additional ATP to be produced. Energy-converting hydrogenases allow some fermenters to generate a proton or sodium motive force by producing H_2 .

Q When fermenting 1.5 glucose to butyrate and acetate, *Clostridium pasteurianum* produces 3 NADH during glycolysis. How does it achieve redox balance?

- 14.20** The bacterium *Propionibacterium* produces propionate, acetate, and CO_2 in a secondary fermentation of lactate. By contrast, *Clostridium kluyveri* produces butyrate and caproate by oxidizing ethanol and reducing acetate.

Q What is the difference between primary and secondary fermentation?

- 14.21** Energy conservation in *Propionigenium*, *Oxalobacter*, and *Malonomonas* is linked to decarboxylation reactions that pump Na^+ or H^+ across the membrane; ATPases use the energy in the ion gradient to form ATP. The reactions catalyzed by these organisms yield insufficient free energy to make ATP by substrate-level phosphorylation but sufficient energy to pump ions.

Q Give an example of a fermentation that does not employ substrate-level phosphorylation.

- 14.22** In syntrophy, two organisms cooperate to degrade a compound that neither can degrade alone. In this process, H_2

produced by one organism is consumed by another. H_2 consumption affects the energetics of the reaction carried out by the H_2 producer, allowing it to make ATP where it otherwise could not.

Q When do syntrophic relationships not involve H_2 transfer?

VII • Hydrocarbon Metabolism

- 14.23** In addition to its role as a terminal electron acceptor, O_2 can also be introduced directly into other substances. In aerobic metabolism, oxygenases introduce atoms of oxygen from O_2 into hydrocarbons. Once oxygenated, aliphatic hydrocarbons can be further degraded by beta-oxidation and aromatic hydrocarbons by ring splitting and oxidation.

Q How do monooxygenases differ from dioxygenases in terms of the reactions they catalyze? Why are oxygenases necessary for the aerobic catabolism of hydrocarbons?

- 14.24** Hydrocarbons can be oxidized under anoxic conditions following addition of the dicarboxylic acid fumarate. Aromatic compounds are catabolized anaerobically by ring reduction and cleavage to form intermediates that can be catabolized in the citric acid cycle.

Q How do denitrifying and sulfate-reducing bacteria degrade hydrocarbons anaerobically and without oxygenases?

APPLICATION QUESTIONS

- The growth rate of the phototrophic purple bacterium *Rhodobacter*, grown *phototrophically* with H_2 as electron donor, is about twice as fast in a medium containing malate as in a medium containing CO_2 as the only carbon source. Discuss the reasons why this is true and list the nutritional class in which we would place *Rhodobacter* when growing under each of the two different conditions.
- A fatty acid such as butyrate cannot be fermented in pure culture, but in many anoxic habitats, fermentative organisms

oxidize it readily. Why can butyrate be fermented in a community of organisms when this process cannot be performed by a pure culture?

- Compare and contrast the methanogenic pathway for growth on $H_2 + CO_2$ in methanogens that have cytochromes with those that lack cytochromes. Why do acetate-degrading (acetoclastic) methanogens not need to fix CO_2 ?

CHAPTER GLOSSARY

Acetogenesis energy metabolism in which acetate is produced from either H_2 plus CO_2 or from organic compounds

Anaerobic respiration a form of respiration in which the terminal electron acceptor is not O_2

Anammox anoxic ammonia oxidation

Anoxygenic photosynthesis photosynthesis in which O_2 is not produced

Antenna pigments light-harvesting chlorophylls or bacteriochlorophylls in photocomplexes that funnel energy to the reaction center

Autotroph an organism capable of biosynthesizing all cell material from CO_2 as the sole carbon source

Bacteriochlorophyll the chlorophyll pigment of anoxygenic phototrophs

Calvin cycle the series of biosynthetic reactions by which most phototrophs and most aerobic chemolithotrophs convert CO_2 into organic compounds

Carboxysomes a polyhedral cellular inclusion of crystalline ribulose biphosphate carboxylase (RuBisCO), the key enzyme of the Calvin cycle

Carotenoid a hydrophobic accessory pigment present along with chlorophyll in photosynthetic membranes

Chlorophyll a light-sensitive, Mg-containing porphyrin of phototrophic organisms that initiates the process of photophosphorylation

Chlorosome a cigar-shaped structure present in the periphery of cells of green sulfur and green nonsulfur bacteria and containing the antenna bacteriochlorophylls (*c*, *d*, or *e*)

Conserve energy to convert energy from chemical reactions or light into a form that can do work, such as ATP

Denitrification anaerobic respiration in which NO_3^- or NO_2^- is reduced to nitrogen gases, primarily N_2

Electron bifurcation (confurcation) an exergonic redox reaction including three simultaneous half reactions whereby 4 electrons ($2 \times 2 e^-$) from a donor are split between an exergonic reduction ($2 \times 1 e^-$) and an endergonic reduction ($2 \times 1 e^-$); the reverse reaction is a *confurcation* causing an endergonic reduction involving two e^- that is driven by an exergonic reduction performed with the other two e^-

Energy-converting hydrogenase a membrane-bound enzyme that uses reduced ferredoxin to reduce protons to H_2 and couples this reaction to the generation of a proton or sodium motive force

Fermentation anaerobic catabolism in which an organic compound is both an electron donor and an electron acceptor and ATP is produced by substrate-level phosphorylation

Heterofermentative in reference to lactic acid bacteria, capable of making a mixture of fermentation products typically including lactate, ethanol, and CO_2 , from the fermentation of glucose

Homofermentative in reference to lactic acid bacteria, producing only lactic acid as a fermentation product

Hydrogenase an enzyme, widely distributed in anaerobic microorganisms, capable of oxidizing or evolving H_2

Methanogen a methane-producing species of the *Archaea*

Methanogenesis the biological production of CH_4

Methanotroph an organism capable of oxidizing methane (CH_4) as an electron donor in energy metabolism

Methyлотroph an organism capable of oxidizing organic compounds that do not contain carbon-carbon bonds; if able to oxidize CH_4 also a methanotroph

Mixotroph an organism that conserves energy from the oxidation of inorganic compounds but requires organic compounds serve as a carbon source

Nanowires electrically conductive type IV pili used to exchange electrons with extracellular objects, either other cells or abiotic structures

Nitrification the microbial oxidation of ammonia to nitrate

Oxygenase an enzyme that catalyzes the incorporation of oxygen from O_2 into organic or inorganic compounds

Oxygenic photosynthesis photosynthesis carried out by cyanobacteria and green plants in which O_2 is evolved

Photosynthesis the series of reactions in which ATP is synthesized by light-driven reactions and CO_2 is fixed into cell material

Phototroph an organism that uses light as its source of energy

Phycobiliprotein the antenna pigment complex in cyanobacteria that contains phycocyanin and allophycocyanin or phycoerythrin coupled to proteins

Phycobilisome an aggregate of phycobiliproteins

Reaction center a photosynthetic complex containing chlorophyll or bacteriochlorophyll and several other components; the initial electron transfer reactions of photosynthetic electron flow occur here

Redox balance having the same number of electrons in the reactants and the products of metabolism

Reducing power the ability to donate electrons in metabolic reactions

Reductive acetyl-CoA pathway a pathway of CO_2 fixation used by obligate anaerobes such as acetogens and methanogens; the pathway reduces CO_2 to acetate and can be reversed to oxidize acetate to CO_2

Reductive dechlorination an anaerobic respiration in which a chlorinated organic compound is used as an electron acceptor, usually with the release of Cl^-

Respiration the process in which an electron donor is oxidized and electrons are passed through electron transport reactions to an external electron acceptor in order to generate a proton motive force and synthesize ATP by oxidative phosphorylation

Reverse citric acid cycle a pathway of CO_2 fixation used in green sulfur bacteria as well as microaerophilic and anaerobic chemolithotrophs

Reverse electron transport a method of generating reducing power, usually in the form of NADH or Fd_{red} , whereby the endergonic reduction of electron carriers is driven by dissipation of a proton motive force

Ribulose monophosphate pathway a reaction series in certain methyлотrophs in which formaldehyde is assimilated into cell material using ribulose monophosphate as the C_1 acceptor molecule

RuBisCO ribulose biphosphate carboxylase, a key enzyme for CO_2 fixation by the Calvin cycle

Secondary fermentation a fermentation in which the substrates are the fermentation products of other organisms

Serine pathway a reaction series in certain methyлотrophs in which CH_2O plus CO_2 are assimilated into cell material by way of the amino acid serine

Stickland reaction the fermentation of an amino acid pair

Syntrophy a process whereby two or more microorganisms cooperate to degrade a substance neither can degrade alone

Thylakoids membrane stacks containing the photosynthetic pigments in cyanobacteria or in the chloroplast of eukaryotic phototrophs

Cyanobacterial Diversity and Environmental Change

Cyanobacteria have had an enormous impact on the Earth for over 2 billion years: They caused Earth's oxygenation and still produce much of the oxygen we breathe today. Cyanobacteria show tremendous ecological diversity, and they are an essential component of healthy ecosystems worldwide. However, the ecological traits that make cyanobacteria so successful also allow them to respond rapidly to environmental change. Human activities alter ecosystem function, and when these activities promote the unrestricted growth of bacteria, the results can be catastrophic.

Intensive agriculture often produces nitrogen and phosphorus runoff that causes ecosystem eutrophication (nutrient enrichment). Phosphorus availability limits cyanobacterial growth in freshwater, and excess phosphorus causes rapid growth of certain cyanobacteria, resulting in harmful blooms. These cyanobacterial blooms release toxins and smother aquatic plants, and subsequent bloom decomposition fuels massive growth of heterotrophic bacteria, causing anoxic conditions that kill aquatic animals. Lake Erie (USA) was once so highly eutrophic it was considered a dead lake, but environmental regulations restricted phosphorus

inputs, restoring its health. However, eutrophication is a problem once again, now largely because of nitrogen runoff.

Microcystis is a genus of freshwater cyanobacteria. While many cyanobacteria can fix N_2 , *Microcystis* cannot, and hence nitrogen enrichment favors the growth of *Microcystis*. Recent blooms in Lake Erie (see natural-color NASA photo, September 2017) were dominated by *Microcystis* species that produce microcystin, a toxin that can kill animals (and humans). A massive *Microcystis* bloom left the city of Toledo, Ohio (USA) without drinking water in 2014, and a similar bloom in Wuxi, China, affected millions of people in 2007.

Elevated temperatures, CO_2 , and nutrient levels associated with climate change are predicted to make such blooms more frequent and more intense in the future. It is thus essential that we understand the ecological diversity of microbes such as cyanobacteria if we are to predict and manage their responses to environmental change.

I • Ecological Diversity Among Microorganisms

Diversity in the microbial world can be described in many different ways. Ecological diversity emphasizes the characteristics of microbial groups in the context of their environments and the microbes they interact with.

Microbial diversity defies simple definitions. If we are to make sense of microbial diversity, we must first identify and measure how one organism differs from another. Microbes differ in many ways, but at a fundamental level we define these differences in terms of three aspects: metabolism, ecology, and phylogeny. Ultimately, these three threads weave together in the tapestry that we call microbial diversity, and only by examining each thread can we understand their connections. We explored microbial metabolic diversity in the previous chapter, and we will explore the phylogenetic diversity of microorganisms in the chapters that follow. Now we will consider and define microbial diversity in terms of ecological differences between microorganisms.

15.1 Making Sense of Microbial Diversity

Metabolic diversity, as explored in the last chapter, is defined in terms of the *cellular processes* that support growth. **Ecological diversity**, which we review in the present chapter, is defined in terms of *microbial interactions* between organisms and their environments. Finally, **phylogenetic diversity**, which we will review in the coming chapters, is defined by *evolutionary relationships* between organisms.

Ecological diversity is the component of microbial diversity that deals with how microbes interact with each other and with their environments. In the microbial world, ecological interactions are often defined by metabolic traits. For example, consider lactic acid bacteria (◀ Section 14.18). These fermentative organisms achieve redox balance by excreting lactic acid as a fermentation product. The excretion of lactic acid also lowers the pH of the environment. Lactic acid bacteria grow well in these acidic conditions, and this acidity inhibits their neutrophilic competitors. Hence, lactic acid production allows these bacteria to interact with their environment and their competitors in a way that facilitates their own growth. In addition to transforming the environment, the products of metabolism often serve as microbial substrates for other microbes, leading to complex mutualistic interactions (◀ Section 14.22). For example, the lactic acid just mentioned is still an energy-rich substance and is actively consumed by propionic acid bacteria, secondary fermenters that ferment lactate into propionate (◀ Section 14.20). Hence, in the microbial world, ecology is interdependent with metabolism.

While it is useful to consider ecological diversity in terms of metabolism, it is incorrect to consider ecological diversity solely in terms of metabolism. Microbes that have similar metabolic traits can still differ substantially in their ecology. For example, organisms that have similar metabolic traits can differ with respect to their morphology, motility, growth rate, environmental

tolerances, mutualisms and antagonisms, as well as their systems of gene regulation and development. All of these traits can have major impacts on microbial distribution and activity in the environment. These complex traits cannot be defined solely in terms of metabolism and are best understood in terms of ecological interactions.

Most fundamentally, phylogenetic diversity deals with the diversity of evolutionary lineages such as phyla, genera, and species. At its broadest, phylogenetic diversity encompasses the genetic and genomic diversity of evolutionary lineages and so can be defined on the basis of either genes or organisms (◀ Section 13.11). Most commonly, though, phylogenetic diversity is defined on the basis of ribosomal RNA gene phylogeny, which is thought to reflect the phylogenetic history of the entire organism (◀ Sections 13.3 and 13.12). Phylogenetic diversity is the overarching theme of our coverage of microbial diversity in Chapters 16–18.

In many cases, metabolic and ecological characteristics align with phylogenetic groups (for example, with the organisms described in Sections 15.3, 15.4, 15.6, 15.7, and 15.17). Microbial ecological diversity, however, often does not correspond with phylogenetic diversity as defined by the 16S ribosomal RNA gene. We will see many examples in this chapter where metabolic and ecological traits are widely distributed among the *Bacteria* and *Archaea* (Figure 15.1), and at least three reasons can account for why metabolic and ecological traits are shared between divergent organisms. The first is *gene loss*, a situation where a trait present in the common ancestor of several lineages is subsequently lost in some lineages but retained in others that over evolutionary time became quite divergent. The second is **convergent evolution**, in which a trait has evolved independently in two or more lineages and is not encoded by homologous genes shared by these lineages. The third is **horizontal gene transfer** (◀ Sections 9.5–9.11 and 13.9–13.11), a situation where genes that confer a particular trait are homologous and have been exchanged between distantly related lineages. Figure 15.1 emphasizes these points by showing how many common metabolisms are dispersed among distinct phylogenetic groups of microbes.

The examples of ecological diversity provided in this chapter are meant to be illustrative and not exhaustive, and we will consider other organisms with important ecological functions in Chapters 16–18 and 20–23. In particular, we will explore the causes and consequences of ecological diversity when we consider the science of microbial ecology in Unit 5 (Chapters 19–23) and bring microbial ecology into a human focus when we consider the human microbiome in Chapter 24.

Check Your Understanding

- Describe a metabolic process that would have a major impact on an organism's ecology.
- What are three reasons that metabolic or ecological traits might not correspond with distinct phylogenetic groups as defined by 16S ribosomal RNA gene sequences?
- Why is it useful to consider microbial diversity in terms of metabolic diversity, ecological diversity, and phylogenetic diversity?

Figure 15.1 Major functional traits mapped across major phyla of *Bacteria* and *Archaea*. The dendrogram shows relationships between microbial phyla as inferred by analysis of 16S ribosomal RNA gene sequences. Blue branches are used to denote phyla of *Bacteria* and red branches denote phyla of *Archaea*. Colored circles indicate phyla that contain at least one species with a functional trait indicated in the color key.

II • Ecological Diversity of Phototrophic *Bacteria*

Light is a powerful energy source and has been tapped by a wide variety of microorganisms—the phototrophs—whose metabolisms share many key attributes yet differ in major ways.

In this section we consider the ecological diversity of phototrophic microorganisms, those microbes that conserve energy from light. We will see that phototrophy is widespread within the domain *Bacteria* and that several distinct types of phototrophs can be defined on the basis of their metabolic and ecological traits.

15.2 Overview of Phototrophic *Bacteria*

The ability to conserve energy from light evolved early in the history of life, when the Earth was anoxic (◀ Section 13.2). Photosynthesis originated within the *Bacteria*, and the first phototrophic organisms were *anoxygenic phototrophs*, organisms that do not generate O_2 as a product of photosynthesis (◀ Section 14.5). Instead of H_2O , these

early phototrophs likely used H_2 , ferrous iron (Fe^{2+}), or H_2S as the electron donor for photosynthesis. Anoxygenic photosynthesis is present in six bacterial phyla: the *Proteobacteria*, *Chlorobi*, *Chloroflexi*, *Firmicutes*, *Acidobacteria*, and *Gemmatimonadetes*. Oxygenic photosynthesis, by contrast, is known only within the *Cyanobacteria* (Figure 15.1). There is extensive metabolic diversity among the anoxygenic phototrophs, which are found in a wide range of habitats. It is clear that horizontal gene exchange has had a major impact on the evolution of photosynthesis and on the distribution of photosynthetic genes across the phylogenetic tree of *Bacteria*.

Phototrophic bacteria have several common features. All phototrophic bacteria use chlorophyll-like pigments and various accessory pigments to harvest energy from light and transfer this energy to a membrane-bound reaction center where it is used to drive electron transfer reactions that ultimately result in the production of ATP (◀ Sections 14.3–14.5). There are two different types of photosynthetic reaction centers: FeS-type reaction centers, which are found in photosystem I of oxygenic phototrophs, and Q-type reaction centers, which are found in photosystem II of oxygenic phototrophs (◀ Sections 14.3–14.6). Both types of reaction centers are present

in *Cyanobacteria* (◀ Section 14.6), whereas only one type or the other is present in anoxygenic phototrophs. In some cases, photosynthetic pigments are found in the cytoplasmic membrane, but often they are present in intracellular photosynthetic membrane systems that originate from invaginations of the cytoplasmic membrane. These internal membranes allow phototrophic bacteria to increase the amount of pigment they contain for better use of light of low intensities.

Many phototrophic bacteria couple light energy to carbon fixation through a variety of different mechanisms (◀ Section 14.2), but not all phototrophs fix CO₂; some instead either prefer or require organic sources of carbon to support growth. We will see that many of the characteristics of phototrophic bacteria, including their membrane systems and photosynthetic pigments, have evolved as a result of niche adaptation for the light environment.

As we begin our tour of ecological diversity, it can be seen that each of the sections in this and the next three chapters begins with a list of a few “Key Genera.” These names are simply meant to familiarize the student with some of the most common microbes in the microbial world and are often the names that appear if one travels beyond this text book to explore the primary scientific literature.

Check Your Understanding

- What form of photosynthesis was most likely the first to appear on Earth?
- What are the different types of photosynthetic reaction centers?
- Why are pigments important to phototrophs?

15.3 *Cyanobacteria*

KEY GENERA: *Prochlorococcus*, *Crocospaera*, *Synechococcus*, *Trichodesmium*, *Oscillatoria*, *Anabaena*

Cyanobacteria comprise a large, morphologically and ecologically heterogeneous group of oxygenic, phototrophic *Bacteria*. As we saw in Section 13.2, these organisms were the first oxygen-evolving phototrophic organisms on Earth, and over billions of years they converted the once anoxic atmosphere of Earth to the oxygenated atmosphere we see today. Though they all share the same form of metabolism, we will see that cyanobacterial species encompass extensive ecological diversity.

Phylogeny and Classification of *Cyanobacteria*

The morphological diversity of the *Cyanobacteria* is impressive (Figure 15.2). Both unicellular and filamentous forms exist, comprising considerable variation in morphology. Cyanobacterial cells range in size from 0.5 μm in diameter to cells as large as 100 μm in diameter. *Cyanobacteria* can be divided into five morphological groups: (1) *Chroococcales* are unicellular, dividing by binary fission (Figure 15.2a); (2) *Pleurocapsales* are unicellular, dividing by multiple fission (colonial) (Figure 15.2b); (3) *Oscillatoriales* are filamentous nonheterocystous forms (Figure 15.2c); (4) *Nostocales* are filamentous, divide along a single axis, and are capable of cellular differentiation (Figure 15.2d); and (5) *Stigonematales* are morphologically similar to *Nostocales* except that cells divide in multiple planes, forming branching filaments (Figure 15.2e). Finally, the **prochlorophytes** are a lineage of unique unicellular *Cyanobacteria* once thought to be distinct but now classified within the *Chroococcales*.

Figure 15.2 The five major morphological types of *Cyanobacteria*. (a) Unicellular, *Gloeotheca*; a single cell measures 5–6 μm in diameter; (b) colonial, *Pleurocapsa*; these structures are >50 μm in diameter and contain hundreds of cells; (c) filamentous, *Lyngbya*; a single cell measures about 10 μm wide; (d) filamentous heterocystous, *Nodularia*; a single cell measures about 10 μm wide; (e) filamentous branching, *Fischerella*; a cell is about 10 μm wide. See how morphological diversity relates to phylogenetic diversity in Figure 15.3.

Figure 15.3 Taxonomically informative traits mapped onto the phylogeny of *Cyanobacteria*. The dendrogram depicts phylogenetic relationships inferred from analysis of conserved protein families in cyanobacterial genomes. Colored circles are used to indicate species traits as indicated by the key. Color shading is used to indicate taxonomic groupings. “*Prochloro.*” is used to indicate *Prochlorococcus*, which is a distinct group within the *Chroococcales*. Note that the *Chroococcales* and *Oscillatoriales* are not monophyletic in origin, meaning that their shared trait of nitrogen fixation has arisen independently on multiple occasions in the phylogeny.

Some of the major morphological classifications of *Cyanobacteria* correspond to coherent phylogenetic groups, but others do not (Figure 15.3). Species of *Pleurocapsales* form a coherent group within the cyanobacteria, indicating that reproduction by multiple fission arose only once in the evolutionary history of *Cyanobacteria* (Figure 15.3). Likewise, species of the *Nostocales* and *Stigonematales* share a common ancestor and form a coherent phylogenetic group, indicating a single origin of cellular differentiation within the *Cyanobacteria* (Figure 15.3). All *Stigonematales* share a single ancestor within the clade composed of *Nostocales* and *Stigonematales*, indicating that the capacity to form branching filaments arose only once within the lineage of *Cyanobacteria* capable of cellular differentiation (Figure 15.3). In contrast, unicellular and simple filamentous *Cyanobacteria* (*Chroococcales* and *Oscillatoriales*, respectively) are dispersed in the cyanobacterial phylogeny, and these morphological groups do not represent coherent evolutionary lineages (Figure 15.3).

Physiology and Photosynthetic Membranes

Cyanobacteria are oxygenic phototrophs and therefore have both FeS-type and Q-type photosystems. All species are able to fix CO₂ by the Calvin cycle, many can fix N₂, and most can synthesize their own vitamins (Sections 3.12 and 4.1). Cells harvest energy from light and fix CO₂ during the day. During the night, cells generate energy by fermentation or aerobic respiration of carbon storage products such as glycogen. While CO₂ is the predominant source of carbon for most species, some *Cyanobacteria* can assimilate simple organic compounds such as glucose and acetate if light is present, a process called *photoheterotrophy*. A few *Cyanobacteria*, mainly filamentous species, can also grow in the dark on glucose or sucrose, using the sugar as both carbon and energy source. Finally, when sulfide concentrations are high, some *Cyanobacteria* are able to switch from oxygenic photosynthesis

to anoxygenic photosynthesis using hydrogen sulfide rather than water as electron donor for photosynthesis (Figure 14.18).

Cyanobacteria have specialized membrane systems called *thylakoids* that increase the ability of cells to harvest light energy (Figure 14.9). Photosynthesis takes place in the thylakoid membrane, a complex and multilayered photosynthetic membrane system containing photopigments and proteins that mediate photosynthesis (Sections 14.3 and 14.4). In most unicellular *Cyanobacteria*, the thylakoid membranes are arranged in regular concentric circles around the periphery of the cytoplasm (Figure 15.4). *Cyanobacteria* produce chlorophyll *a*, and most also have characteristic pigments called **phycobilins** (Figure 14.14), which function as accessory pigments in photosynthesis. One class of phycobilins, *phycocyanins*, are blue and, together with the green chlorophyll *a*, are responsible for the blue-green color of most cyanobacteria. Some *Cyanobacteria* produce *phycoerythrin*, a red phycobillin, and species producing phycoerythrin

Figure 15.4 Thylakoids in *Cyanobacteria*. Electron micrograph of a thin section of the cyanobacterium *Synechococcus lividus*. A cell is about 5 μm in diameter. Note thylakoid membranes running parallel to the cell wall.

are red or brown. Photopigments are fluorescent and emit light when visualized using a fluorescence microscope; chlorophyll *a*, for example, fluoresces bright red (Figure 15.5). Prochlorophytes, such as *Prochlorococcus* and *Prochloron*, are unique among *Cyanobacteria* in that all members of this group contain chlorophyll *a* and *b* but do not contain phycobilins.

Cellular Structures and Motility

The cell wall of *Cyanobacteria* contains peptidoglycan and is structurally similar to that of other gram-negative bacteria. And, like many bacteria, *Cyanobacteria* possess several mechanisms for motility but do not contain flagella. Many cyanobacteria exhibit gliding motility (◀ Section 2.10). Gliding occurs only when a cell or filament is in contact with a solid surface or with another cell or filament. In some *Cyanobacteria*, gliding is not a simple translational movement but is accompanied by rotations, reversals, and flexing of filaments (◀ Figure 2.37b). Most gliding species exhibit directional movement toward light (phototaxis), and chemotaxis (◀ Section 2.11) may occur as well. *Synechococcus* exhibits an unusual form of swimming motility that does not require flagella or any other extracellular organelle. The cell surface of *Synechococcus* has specialized proteins that provide direct thrust by way of a mechanism that has yet to be resolved. Gas vesicles (◀ Section 2.7) are also found in a variety of aquatic *Cyanobacteria* and are important in positioning cells in the water column. The function of gas vesicles is to regulate cell buoyancy such that cells can remain in a position in the water column where light intensity is optimal for photosynthesis.

Cyanobacteria are able to form a variety of structures associated with energy storage, reproduction, and survival. Many *Cyanobacteria* produce extensive mucilaginous envelopes, or sheaths, that bind groups of cells or filaments together (Figure 15.2a). Some filamentous cyanobacteria form *hormogonia* (Figure 15.6), short, motile filaments that break off from longer filaments to facilitate dispersal in times of stress. Some species also form resting structures called *akinetes* (Figure 15.6c), which protect the organism during periods of darkness,

Figure 15.5 Phycocyanin fluorescence in *Cyanobacteria*. Fluorescence micrograph of *Spirulina*. Filaments consist of chains of helical cells with each cell approximately 5 μm wide.

Figure 15.6 Structural differentiation in filamentous *Cyanobacteria*. (a) Initial stage of hormogonium formation in *Oscillatoria*. Notice the empty spaces where the hormogonium is separating from the filament. (b) Hormogonium of a smaller *Oscillatoria* species. Notice that the cells at both ends are rounded. Cells are about 10 μm wide. Differential interference contrast microscopy. (c) Akinete (resting spore) of *Anabaena* in a phase-contrast micrograph, cells about 5 μm wide.

desiccation, or cold. Akinetes are cells with thickened outer walls. When conditions improve, akinetes germinate by breaking down their outer wall and initiating growth of a new vegetative filament. Many *Cyanobacteria* also form a structure called *cyanophycin*. This structure is a copolymer of aspartic acid and arginine and is a nitrogen storage product; when nitrogen in the environment becomes deficient, cyanophycin is broken down and used as a cellular nitrogen source. Many species of the *Nostocales* and *Stigonematales* are also able to form heterocysts, as discussed next.

Heterocysts and Nitrogen Fixation

Many *Cyanobacteria* are capable of nitrogen fixation (Figure 15.3). The nitrogenase enzyme, however, is inhibited by oxygen, and thus nitrogen fixation cannot occur along with oxygenic photosynthesis (◀ Section 3.12). *Cyanobacteria* have evolved several regulatory mechanisms for separating nitrogenase activity from photosynthesis

Figure 15.7 Marine *Cyanobacteria* that fix N_2 . (a) Unicellular *Crocosphaera*-like cells in the process of dividing; cells are approximately 5 μm diameter. (b) Colonial “tuft” of *Trichodesmium*. The tuft is composed of many attached, undifferentiated, unbranched filaments and has a diameter of approximately 100 μm . (c) A diatom containing the cyanobacterial symbiont *Richelia* (scale in micrometers). The *Richelia* symbiont is an unbranched filament with a terminal heterocyst; cells are about 5 μm wide.

(◀ Section 8.9). For example, many unicellular *Cyanobacteria*, such as *Cyanothece* and *Crocosphaera* (Figure 15.7a), fix nitrogen only at night when photosynthesis does not occur. In contrast, the filamentous cyanobacteria *Trichodesmium* (Figure 15.7b) fixes nitrogen only during the day through a mechanism that remains unclear but appears to require transient suppression of photosynthetic activity (and its O_2 production) within filaments. Finally, many filamentous *Cyanobacteria* of the *Nostocales* and *Stigonematales* facilitate nitrogen fixation by forming specialized cells called *heterocysts*, either on the ends of filaments (Figure 15.8a, b) or along the filament (Figure 15.8c, d).

Heterocysts arise from differentiation of vegetative cells and are the sites of nitrogen fixation in heterocystous *Cyanobacteria*. Heterocysts are surrounded by a thickened cell wall that slows the diffusion

of O_2 into the cell and permits nitrogenase activity to occur in an anoxic environment. Heterocysts lack photosystem II, the oxygen-evolving photosystem that generates reducing power from H_2O (◀ Section 14.6), and thus do not fluoresce as strongly as vegetative cells (Figure 15.8). Without photosystem II, heterocysts are unable to fix CO_2 and thus lack the necessary electron donor (pyruvate) for nitrogen fixation. However, heterocysts have intercellular connections with adjacent vegetative cells that allow for mutual exchange of materials between these cells. Fixed carbon is imported by the heterocyst from adjacent vegetative cells, and this is oxidized to yield electrons for nitrogen fixation. The products of photosynthesis move from vegetative cells to heterocysts, and fixed nitrogen moves from heterocysts to vegetative cells (◀ Figure 8.21).

Figure 15.8 Heterocysts. Differentiation of heterocysts causes the loss of photopigments and inability to carry out photosynthesis. (a) Phase-contrast micrograph of *Calothrix* with terminal heterocysts. (b) Fluorescence micrograph of the same *Calothrix* filaments; cells are about 10 μm wide. (c) Phase-contrast micrograph of *Fischerella*. (d) Fluorescence micrograph of the same *Fischerella* filaments; cells are about 10 μm wide. See how heterocyst formation is regulated at the genetic level in the well-studied cyanobacterium *Anabaena* in Figure 8.21.

Ecology of Cyanobacteria

Cyanobacteria are of central importance to the productivity of the oceans. Small unicellular *Cyanobacteria*, such as *Synechococcus* and *Prochlorococcus* (► Section 20.11), are the most abundant phototrophs in the oceans. Together these organisms contribute 80% of marine photosynthesis and 35% of all photosynthetic activity on Earth.

Cyanobacterial nitrogen fixation represents the dominant input of new nitrogen into vast segments of Earth's oceans, particularly in oligotrophic tropical and subtropical waters. Marine nitrogen fixation is dominated by two groups of *Cyanobacteria*, the unicellular species, such as *Crocospaera*, and the filamentous *Trichodesmium*. *Crocospaera* (Figure 15.7a) and relatives dominate nitrogen fixation in most of the Pacific Ocean and are widespread in tropical and subtropical habitats. *Trichodesmium* is the dominant nitrogen-fixer in the North Atlantic Ocean and parts of the Pacific where dissolved iron concentrations are elevated. *Trichodesmium* forms macroscopically visible tufts of filaments (Figure 15.7b) and relies on gas vesicles to remain suspended in the photic zone, where it is often observed in dense masses of cells called *blooms*. In addition, other marine nitrogen-fixers including species of *Calothrix* and *Richelia* form symbiotic associations with diatoms (Figure 15.7c); these symbiotic associations are often observed in tropical and subtropical oceans. Finally, heterocystous cyanobacteria such as *Nodularia* (Figure 15.2d) and *Anabaena* can sometimes dominate nitrogen fixation in cold waters of the Northern Hemisphere and are often observed in the Baltic Sea.

Cyanobacteria are also widely found in terrestrial and freshwater environments. In general, they are more tolerant of environmental extremes, particularly extremes of desiccation, than are eukaryotic algae. *Cyanobacteria* are often the dominant or sole oxygenic phototrophic organisms in hot springs, saline lakes, desert soils, and other extreme environments. In some of these environments, cyanobacterial mats of variable thickness may form (► Figure 20.8). Freshwater lakes, especially those rich in inorganic nutrients, often develop blooms of *Cyanobacteria*, especially

in late summer when temperatures are warmest (► Figures 20.1 and 20.19b). A few *Cyanobacteria* are symbionts of liverworts, ferns, and cycads, and a number are phototrophic components of lichens, a symbiosis between a phototroph and a fungus (► Section 23.1).

Several metabolic products of *Cyanobacteria* are of considerable practical importance. Some *Cyanobacteria* produce potent neurotoxins, and toxic blooms may form when massive accumulations of *Cyanobacteria* develop. Animals ingesting water containing these toxic products may be killed. Many *Cyanobacteria* are also responsible for the production of earthy odors and flavors in some freshwater, and if such waters are used as drinking water sources, aesthetic problems may arise. The major compound produced is geosmin, a substance also produced by many actinomycetes (► Section 16.12).

Check Your Understanding

- What are the differentiating properties of the five major morphological groups of *Cyanobacteria*?
- What is a heterocyst and what is its function?
- Why are cyanobacteria such as *Synechococcus* and *Prochlorococcus* so important to the global oxygen budget?

15.4 Purple Sulfur Bacteria

KEY GENERA: *Chromatium*, *Thermochromatium*, *Ectothiorhodospira*

Purple sulfur bacteria are anoxygenic phototrophs that use hydrogen sulfide (H_2S) as an electron donor for photosynthesis (◄ Figure 14.5). Purple sulfur bacteria are a phylogenetically coherent group found within the order *Chromatiales* in the *Gammaproteobacteria*.

Purple sulfur bacteria are generally found in illuminated anoxic zones where H_2S is present. Such habitats occur commonly in lakes, marine sediments, and “sulfur springs,” where H_2S produced geochemically or biologically can support the growth of purple sulfur bacteria (Figure 15.9).

Figure 15.9 Anoxygenic phototrophs in aquatic environments. Groundwater passing through sedimentary rock can introduce sulfur minerals into lakes and ponds. (a) Purple sulfur bacteria, such as *Lamprocystis roseopersicina* (shown here), grow on the sediment of a spring-fed pool and float to the surface (by virtue of their gas vesicles) when disturbed. The purple color is from the photopigments of the purple sulfur bacteria and the green color is from cells of the alga *Spirogyra*.

(b) Sample of water from a depth of 7 m in Lake Mahoney, British Columbia; the major phototroph is the purple sulfur bacterium *Amoebobacter purpureus*. These phototrophs grow in a dense purple cloud at the chemocline, where sulfide-rich bottom water is exposed to light from the surface. (c) Phase-contrast photomicrograph of water from the chemocline of Lake Dagow, Germany, containing several purple and green sulfur bacteria. Abbreviations: Tr, *Thiopedia rosea* (purple

sulfur bacteria); Ca, green sulfur bacteria partially disaggregated from “*Chlorochromatium aggregatum*” (a phototrophic consortium, see Section 15.6); Cn, *Chloronema* sp. (green nonsulfur bacteria, see Section 15.7); Pr, “*Pelochromatium roseum*” (a phototrophic consortium, ► Section 23.2); Plr, *Planktothrix rubescens* (cyanobacteria, Section 15.3). Gas vesicles (◄ Section 2.7) within Tr, Cn, and Plr cells cause them to appear refractile. Each Cn cell is about 5 μm long.

Purple sulfur bacteria are also commonly found in microbial mats (► Section 20.5) and in salt marsh sediments. The characteristic color of purple sulfur bacteria comes from their carotenoids, accessory pigments involved in light harvesting (◄ Section 14.4). These bacteria use a Q-type photosystem (◄ Figure 14.16), contain either bacteriochlorophyll *a* or *b*, and carry out CO₂ fixation by the Calvin cycle (◄ Section 3.12).

During autotrophic growth of purple sulfur bacteria, H₂S is oxidized to elemental sulfur (S⁰), which is deposited as sulfur granules (Figure 15.10). When sulfide is limiting, the sulfur is used as an electron donor for photosynthesis, resulting in the oxidation of S⁰ to sulfate (SO₄²⁻). Many purple sulfur bacteria can also use other reduced sulfur compounds as photosynthetic electron donors; for example, thiosulfate (S₂O₃²⁻) is commonly used to grow laboratory cultures.

The purple sulfur bacteria form two families: the *Chromatiaceae* and the *Ectothiorhodospiraceae*. Species of the two families are readily distinguished by the location of sulfur granules and by their photosynthetic membranes. *Chromatiaceae*, including the genera *Chromatium* and *Thiocapsa*, store S⁰ granules *inside* their cells (in the periplasmic space) and have vesicular intracellular photosynthetic membrane systems (Figure 15.11b). These organisms are common in stratified lakes containing sulfide and in the anoxic sediments of salt marshes.

Figure 15.10 Bright-field and phase-contrast photomicrographs of purple sulfur bacteria. (a) *Chromatium okenii*; cells are about 5 μm wide. Note the globules of elemental sulfur inside the cells. (b) *Thiopirillum jenense*, a very large, polarly flagellated spiral; cells are about 30 μm long. Note the sulfur globules. (c) *Thiopodia rosea*; cells are about 1.5 μm wide. (d) Phase-contrast micrograph of cells of *Ectothiorhodospira mobilis*; cells are about 0.8 μm wide. Note external sulfur globules (arrow).

Figure 15.11 Membrane systems of phototrophic purple bacteria as revealed by transmission electron microscopy. (a) *Ectothiorhodospira mobilis*, showing the photosynthetic membranes in flat sheets (lamellae). (b) *Allochromatium vinosum*, showing the membranes as individual, spherical vesicles.

Ectothiorhodospiraceae, including the two main genera *Ectothiorhodospira* and *Halorhodospira*, oxidize H₂S to S⁰ that is deposited *outside* the cell (Figure 15.10d) and have lamellar intracellular photosynthetic membrane systems (Figure 15.11a). These genera are also interesting because many species are extremely halophilic (salt loving) or alkaliphilic (alkalinity loving) and are among the most extreme in these characteristics of all known *Bacteria*. These organisms are typically found in saline lakes, soda lakes, and salterns, where abundant levels of SO₄²⁻ support sulfate-reducing bacteria (► Section 21.4 and Section 15.11), the organisms that produce H₂S.

Purple sulfur bacteria are often observed in high density in meromictic (permanently stratified) lakes. Meromictic lakes form layers because they have denser (usually saline) water on the bottom and less dense water (usually freshwater) nearer the surface. If sufficient sulfate is present to support sulfate reduction, sulfide is produced in the sediments and diffuses upward into the anoxic bottom waters. The presence of sulfide and light in the anoxic layers of the lake allows purple sulfur bacteria to form dense cell masses (Figure 15.9b, c), usually in association with green phototrophic bacteria.

Thermochromatium, a thermophilic purple sulfur bacterium, inhabits sulfidic hot springs where it forms thin microbial biofilms

(◀ Section 4.9 and Figure 4.17a). The only known species of *Thermochromatium*, *T. tepidum*, has unique absorption properties and has become a model organism for the study of energy transfer from light-harvesting (antenna) pigments to the photosynthetic reaction center (◀ Section 14.5).

Check Your Understanding

- What is the source of the purple color from which the purple sulfur bacteria get their name?
- Where would you expect to find purple sulfur bacteria in nature?

15.5 Purple Nonsulfur Bacteria and Aerobic Anoxygenic Phototrophs

Purple Nonsulfur Bacteria

KEY GENERA: *Rhodospirillum*, *Rhodoferrax*, *Rhodopseudomonas*, *Rhodobacter*

The **purple nonsulfur bacteria** are the most metabolically versatile of all microbes. Despite their name, they are not always purple; these organisms synthesize an array of carotenoids (◀ Section 14.4) that can lend them a variety of spectacular colors (Figure 15.12). Together, these pigments give purple bacteria their colors, usually purple, red, or orange. Purple nonsulfur bacteria are typically photoheterotrophs (a condition where light is the energy source and an organic compound is the carbon source), and species are able to use a wide range of carbon sources and electron donors for photosynthesis, including organic acids, amino acids, alcohols, sugars, and even aromatic compounds like benzoate or toluene. Like purple sulfur bacteria, purple nonsulfur bacteria use a Q-type photosystem and contain either bacteriochlorophyll *a* or *b*. The purple nonsulfur bacteria are phylogenetically and morphologically diverse (Figure 15.13) and reside within the *Alphaproteobacteria* (e.g., *Rhodospirillum*, *Rhodobacter*, *Rhodopseudomonas*) or *Betaproteobacteria* (e.g., *Rubrivivax*, *Rhodoferrax*).

One interesting characteristic shared by all species of purple nonsulfur bacteria (including the aerobic species to be discussed in the next subsection) is the presence of a “photosynthetic gene cluster” (PGC). The PGC is a set of several connected operons whose genes encode the necessary proteins to carry out anoxygenic photosynthesis: pigment biosynthesis proteins, light-harvesting and reaction center proteins, and a variety of regulatory and other photosynthesis proteins (◀ Section 14.5). Gene co-localization enables coordinated regulation of expression, but such co-localization also facilitates horizontal gene transfer. Genome sequence data indicates that horizontal transfer of PGC likely contributed to the evolution of phototrophy in lineages such as *Gemmatimonadetes* and *Chloroflexi*.

Purple nonsulfur bacteria can conserve energy through a variety of metabolic processes. For example, some species can grow photoautotrophically using H_2 , low levels of H_2S , or even ferrous iron (Fe^{2+}) as the electron donor for photosynthesis with CO_2 fixation carried out by the Calvin cycle. Most species are also able to grow in darkness by using aerobic respiration of organic or even some

Figure 15.12 Photograph of liquid cultures of phototrophic purple bacteria showing the color of species with various carotenoid pigments. All species contain bacteriochlorophyll *a*. The blue culture is a carotenoidless mutant strain of *Rhodospirillum rubrum* showing that bacteriochlorophyll *a* is actually blue. The bottle on the far right (*Rhodobacter sphaeroides* strain G) lacks one of the carotenoids of the wild type and thus is less red and more green.

Figure 15.13 Representatives of several genera of purple nonsulfur bacteria. (a) *Phaeospirillum fulvum*; cells are about 3 μm long. (b) *Rhodoblastus acidophilus*; cells are about 4 μm long. (c) *Rhodobacter sphaeroides*; cells are about 1.5 μm wide. (d) *Rhodopila globiformis*; cells are about 1.6 μm wide. (e) *Rhodocyclus purpureus*; cells are about 0.7 μm in diameter. (f) *Rhodomicrobium vannielii*; cells are about 1.2 μm wide.

inorganic compounds; synthesis of the photosynthetic machinery is typically repressed by O_2 . Finally, some species can also grow by fermentation or anaerobic respiration using a variety of electron donors and acceptors.

Enrichment and isolation of purple nonsulfur bacteria is easy using a mineral-salts medium supplemented with an organic acid (for example, acetate, malate, or succinate) as carbon source. Such media, inoculated with a mud, lake water, or sewage sample and incubated anaerobically in the light, invariably select for purple nonsulfur bacteria. Enrichment cultures can be made even more selective by omitting fixed nitrogen sources (for example, ammonia) or organic nitrogen sources (for example, yeast extract or peptone) from the medium and supplying a gaseous headspace of N_2 . Virtually all purple nonsulfur bacteria can fix N_2 (◀ Section 3.12) and will thrive under such conditions, rapidly outcompeting other bacteria.

Aerobic Anoxygenic Phototrophs

KEY GENERA: *Roseobacter*, *Erythrobacter*

The **aerobic anoxygenic phototrophs** are obligatory aerobic heterotrophs that use light as a supplemental source of energy to support growth. Like purple nonsulfur bacteria, aerobic anoxygenic phototrophs are phylogenetically diverse and are *Alphaproteobacteria* or *Betaproteobacteria*. Their primary physiological difference from the purple nonsulfur bacteria is that aerobic anoxygenic phototrophs are strict heterotrophs and employ anoxygenic photosynthesis only under *oxic* conditions as a supplemental source of energy. Aerobic anoxygenic phototrophs contain bacteriochlorophyll *a* and a Q-type photosystem but are unable to fix CO_2 and thus rely on organic forms of carbon as their carbon source. Carotenoids of various types lend colors of yellow, orange, or pink to cultures.

Aerobic anoxygenic phototrophs are only able to photosynthesize when grown on a day/night cycle. Under these conditions, bacteriochlorophyll *a* is made only in the dark and then used to conserve energy by photophosphorylation when the light returns. Aerobic anoxygenic phototrophs can account for as much as a

quarter of the microbial community inhabiting coastal marine waters and 5% of gross photosynthesis in such systems (▶ Section 20.11). Common genera found in coastal marine habitats include *Roseobacter* and *Erythrobacter*.

Check Your Understanding

- What are some similarities between purple nonsulfur bacteria and aerobic anoxygenic phototrophs? What are the differences between these two groups?
- Where would you expect to find aerobic anoxygenic phototrophs?

15.6 Green Sulfur Bacteria

KEY GENERA: *Chlorobium*, *Chlorobaculum*, *Prosthecochloris*, "*Chlorochromatium*"

Green sulfur bacteria are a phylogenetically coherent group of anoxygenic phototrophs that forms the phylum *Chlorobi*. Green sulfur bacteria have little metabolic versatility, and they are typically nonmotile and strictly anaerobic anoxygenic phototrophic bacteria. The group is also morphologically restricted and includes primarily short to long rods (Figure 15.14).

Like purple sulfur bacteria, green sulfur bacteria oxidize hydrogen sulfide (H_2S) as an electron donor for autotrophic growth, oxidizing it first to sulfur (S^0) and then to sulfate (SO_4^{2-}). But unlike most purple sulfur bacteria, the S^0 produced by green sulfur bacteria is deposited only outside the cell (Figure 15.14a). Autotrophy is supported not by the reactions of the Calvin cycle, as in purple bacteria, but instead by a reversal of steps in the citric acid cycle (◀ Section 14.2), a unique means of autotrophy in phototrophic bacteria.

Pigments and Ecology

Green sulfur bacteria contain bacteriochlorophyll *c*, *d*, or *e* and house these pigments in unique structures called **chlorosomes**

Figure 15.14 Phototrophic green sulfur bacteria. (a) Phase-contrast micrograph of *Chlorobium limicola*; cells are about $0.8\ \mu m$ wide. Note the spherical sulfur granules deposited extracellularly. (b) Phase-contrast micrograph of *Chlorobium clathratiforme*, a bacterium forming a three-dimensional network; cells are about $0.8\ \mu m$ wide. (c) Scanning electron micrograph of cells of *Prosthecochloris aestuarii* showing numerous prosthecae on each cell; cells are about $1.2\ \mu m$ long. (d) Transmission electron micrograph of a *P. aestuarii* cell showing chlorosomes (arrow) within prosthecae.

F. Rudy Turner and Michael T. Madigan

Figure 15.15 The thermophilic green sulfur bacterium *Chlorobaculum tepidum*. Transmission electron micrograph. Note chlorosomes (arrow) in the cell periphery. A cell is about 0.7 μm wide.

(◀ Section 14.3 and **Figure 15.15**). A small amount of bacteriochlorophyll *a* is present in the reaction center and FMO protein, the latter of which connects the chlorosome to the cytoplasmic membrane (◀ Figure 14.11*b*). Chlorosomes are oblong, bacteriochlorophyll-rich bodies bounded by a thin, nonunit membrane and attached to the cytoplasmic membrane in the periphery of the cell (Figure 15.15 and ▶ Figure 14.11). Chlorosomes function to funnel energy into the photosystem, and this eventually leads to ATP synthesis. Unlike purple anoxygenic phototrophs, green sulfur bacteria use an FeS-type photosystem. Both green- and brown-colored species of green sulfur bacteria are known, the brown-colored species containing bacteriochlorophyll *e* and carotenoids that turn dense cell suspensions brown (**Figure 15.16**).

Like purple sulfur bacteria (Section 15.4), green sulfur bacteria live in anoxic, sulfidic, illuminated aquatic environments. However, the chlorosome is a very efficient light-harvesting structure, which allows green sulfur bacteria to grow at light intensities much lower than those required by other phototrophs. Green

Deborah O. Jung

Figure 15.16 Green and brown chlorobia. Tube cultures of (a) *Chlorobaculum tepidum* and (b) *Chlorobaculum phaeobacteroides*. Cells of *C. tepidum* contain bacteriochlorophyll *c* and green carotenoids, and cells of *C. phaeobacteroides* contain bacteriochlorophyll *e* and isorenieratene, a brown carotenoid. The structures of bacteriochlorophylls *c* and *e* and of green bacteria carotenoids were shown in Figures 14.7 and 14.13, respectively.

sulfur bacteria also tend to have a greater tolerance of H_2S than do other anoxygenic phototrophs. As a result, green sulfur bacteria are typically found at the greatest depths of all phototrophic microorganisms in lakes or microbial mats, where light intensities are low and H_2S levels the highest. As an example, a species of green sulfur bacteria isolated from a deep-sea hydrothermal vent (▶ Section 20.16) was found to be growing phototrophically on the weak glow of infrared radiation emitted from the geothermally heated rock.

Although most green sulfur bacteria are freshwater species, some are marine and at least one species is thermophilic. *Prosthecochloris* is a marine species whose cells form extensions of the cytoplasm and cell wall called *prosthecae* (see Section 15.18 and Figure 15.53) that contain chlorosomes (Figure 15.14*c, d*). Some *Prosthecochloris* species inhabit saline lakes and appear to be the only green sulfur bacteria to be widespread outside of freshwater habitats. *Chlorobaculum tepidum* (Figure 15.15) is thermophilic and forms dense microbial mats in high-sulfide hot springs. *C. tepidum* also grows rapidly and is amenable to genetic manipulation by both conjugation and transformation (Chapter 9). In addition, *C. tepidum* can use thio-sulfate as an electron donor for autotrophic CO_2 fixation, a property not universal among green sulfur bacteria. Because of these features, *C. tepidum* has become the model organism for studying the molecular biology of green sulfur bacteria.

Green Sulfur Bacteria Consortia

Certain species of green sulfur bacteria form an intimate two-membered association, called a **consortium**, with a chemoorganotrophic bacterium. In the consortium, each organism benefits, and thus a variety of such consortia containing different phototrophic and chemotrophic components probably exist in nature. The phototrophic component, called the *epibiont*, is physically attached to the nonphototrophic central cell (**Figure 15.17**) and communicates with it in various ways (▶ Section 23.2).

The name “*Chlorochromatium aggregatum*” (not a formal name because this is a mixed culture) has been used to describe a commonly observed green-colored consortium that is green because the epibionts are green sulfur bacteria that contain green-colored carotenoids (Figure 15.17*b* and Figure 15.9*c*). Evidence that the epibionts are indeed green sulfur bacteria comes from pigment analyses, the presence of chlorosomes (Figure 15.17*d*), and phylogenetic staining (Figure 15.17*c*). A structurally similar consortium called “*Pelochromatium roseum*” is brown because its epibionts produce brown-colored carotenoids (Figure 15.9*c* and ▶ Figures 23.3–23.5). We examine the symbiotic nature of the *Chlorochromatium* consortium in more detail in (▶ Section 23.2).

Check Your Understanding

- Which pigments are present in the chlorosome?
- What evidence exists that the epibionts of green bacterial consortia are truly green sulfur bacteria?

Figure 15.17 “*Chlorochromatium aggregatum*.” Consortia of green sulfur bacteria and a chemoorganotroph (see also Figure 15.9 and ► Section 23.2). (a) In a phase-contrast micrograph, the nonphototrophic central organism is lighter in color than the pigmented phototrophic bacteria. (b) Green carotenoids lend their color to the phototrophs in a differential interference contrast micrograph. (c) A fluorescence micrograph shows the cells stained with a fluorescent probe specific for green sulfur bacteria. (d) Transmission electron micrograph of a cross section through a single consortium; note the chlorosomes (arrows) in the epibionts. The entire consortium is about 3 μm in diameter.

15.7 Green Nonsulfur Bacteria

KEY GENERA: *Chloroflexus*, *Heliothrix*, *Roseiflexus*

Green nonsulfur bacteria, which are also called *filamentous anoxygenic phototrophs*, are anoxygenic phototrophs of the phylum *Chloroflexi*. The latter contains several distinct lineages, one of which, the class *Chloroflexi*, contains green nonsulfur bacteria. The remainder of the phylum contains metabolically diverse organisms including both aerobic and anaerobic chemoorganotrophs as well as the *Dehalococcoidetes*, a group of dehalogenating bacteria that use halogenated organic compounds as electron acceptors in anaerobic respiration (◄ Section 14.13). Analyses of 16S ribosomal RNA sequences from environmental samples (► Sections 19.6 and 19.8) indicate that species of the phylum *Chloroflexi* are widespread and that most species in the phylum have yet to be cultivated in isolation; thus, the extent of the metabolic diversity of this phylum remains unclear.

All cultured representatives of the green nonsulfur bacteria are filamentous bacteria that are capable of gliding motility. *Chloroflexus*, one of the most studied of the green nonsulfur bacteria, forms thick

microbial mats in neutral to alkaline hot springs along with thermophilic cyanobacteria (Figure 15.18; ► Figure 20.8b). Green nonsulfur bacteria grow best as photoheterotrophs using simple carbon sources as electron donors for photosynthesis. However, growth also occurs photoautotrophically using H₂ or H₂S as electron donors for photosynthesis. The 3-hydroxypropionate bi-cycle, a pathway of CO₂ incorporation unique to only a few *Bacteria* and *Archaea*, supports autotrophic growth (◄ Section 14.2). Most green nonsulfur bacteria also grow well in the dark by aerobic respiration of a wide variety of carbon sources.

The photosynthetic features of the green nonsulfur bacteria form a “hybrid” between those of both green sulfur bacteria (Section 15.6) and purple phototrophic bacteria (Sections 15.4, 15.5). Green nonsulfur bacteria have reaction centers that contain bacteriochlorophyll *a* and chlorosomes that contain bacteriochlorophyll *c* and in this way are similar to green sulfur bacteria (Figure 15.15). However, in contrast

Figure 15.18 Green nonsulfur bacteria. (a) Phase-contrast micrograph of the anoxygenic phototroph *Chloroflexus aurantiacus*; cells are about 1 μm in diameter. (b) Phase-contrast micrograph of the large phototroph *Oscillochloris*; cells are about 5 μm wide. The brightly contrasting material on the top is a holdfast, used for attachment. (c) Phase-contrast micrograph of filaments of a *Chloronema* species; the cells are wavy filaments and about 2.5 μm in diameter. (d) Tube cultures of *C. aurantiacus* (right) and *Roseiflexus* (left). *Roseiflexus* is yellow because it lacks bacteriochlorophyll *c* and chlorosomes.

Figure 15.19 The unusual lipids of *Thermomicrobium*. (a) Membrane lipids from *Thermomicrobium roseum* contain long-chain diols like the one shown here (1,2-nonadecanediol). Note that unlike the lipids of other *Bacteria* or of *Archaea*, neither ester- nor ether-linked side chains are present. (b) To form a bilayer membrane, dialcohol molecules oppose each other at the methyl groups, and the —OH groups are the inner and outer hydrophilic surfaces. Small amounts of the diols have fatty acids esterified to the secondary —OH group (shown in red), whereas the primary —OH group (shown in green) can bond with a hydrophilic molecule like phosphate.

to green sulfur bacteria, green nonsulfur bacteria contain a Q-type photosynthetic reaction center (◀ Section 14.5 and Figure 14.16) and in this respect resemble purple bacteria.

Other Chloroflexi

In addition to *Chloroflexus*, other phototrophic green nonsulfur bacteria include the thermophile *Heliobacter* and the large-celled mesophiles *Oscillochloris* (Figure 15.18b) and *Chloronema* (Figure 15.18c). *Oscillochloris* and *Chloronema* form rather large cells, 2–5 μm wide and up to several hundred micrometers long (Figure 15.18c). Species of both genera inhabit freshwater lakes containing H_2S . *Roseiflexus* and *Heliobacter* are similar to *Chloroflexus* in their filamentous morphology and thermophilic lifestyle but differ in a major photosynthetic property. *Roseiflexus* and *Heliobacter* lack bacteriochlorophyll *c* and chlorosomes and thus more closely resemble purple phototrophic bacteria (Sections 15.4, 15.5) than *Chloroflexus*. This can be seen in cultures of *Roseiflexus* that are yellow-orange instead of green from their extensive carotenoid pigments and lack of bacteriochlorophyll *c* (Figure 15.18d).

Thermomicrobium is a nonphototrophic genus of *Chloroflexi* and a strictly aerobic, gram-negative rod, growing optimally in complex

media at 75°C. Besides its phylogenetic properties, *Thermomicrobium* is also of interest because of its membrane lipids (Figure 15.19). Recall that the lipids of *Bacteria* and *Eukarya* contain fatty acids esterified to glycerol (◀ Section 2.1). By contrast, the lipids of *Thermomicrobium* are formed on 1,2-dialcohols instead of glycerol and have neither ester nor ether linkages (Figure 15.19; ◀ Section 2.1). In addition, cells of *Thermomicrobium* contain only small amounts of peptidoglycan (◀ Section 2.3), and the cell wall is composed primarily of protein.

Check Your Understanding

- In what ways do *Chloroflexus* and *Roseiflexus* resemble *Chlorobium*? *Rhodobacter*?
- What is unique about *Thermomicrobium*?

15.8 Other Phototrophic Bacteria

Heliobacteria

KEY GENERA: *Heliobacterium*, *Heliorestis*

Heliobacteria are a phylogenetically coherent group of phototrophic gram-positive *Bacteria* found within the phylum *Firmicutes* (▶ Section 16.8). The heliobacteria are anoxygenic phototrophs that have an FeS-type photosystem (◀ Section 14.5) and that produce a unique pigment, bacteriochlorophyll *g* (◀ Figure 14.7). Heliobacteria grow photoheterotrophically using a narrow range of organic compounds including pyruvate, lactate, acetate, or butyrate, and the group contains five genera: *Heliobacterium*, *Heliophilum*, *Heliorestis*, *Heliomonas*, and *Heliobacillus*. All known heliobacteria form rod-shaped or filamentous cells (Figure 15.20), although *Heliophilum* is unusual because its cells form into bundles (Figure 15.20b) that are motile as a unit.

Heliobacteria are strict anaerobes, but in addition to phototrophic growth, they can grow chemotrophically in darkness by pyruvate fermentation (as can many clostridia, close relatives of the heliobacteria). Heliobacteria produce endospores, the highly resistant structures produced by certain gram-positive bacteria (◀ Section 2.8). Like the endospores of *Bacillus* or *Clostridium* species, the endospores of heliobacteria (Figure 15.20c) contain elevated calcium (Ca^{2+}) levels and the signature molecule of the endospore, dipicolinic acid. Heliobacteria reside in soil, especially paddy (rice) field soils, where

Figure 15.20 Cells and endospores of heliobacteria. (a) Electron micrograph of *Heliobacillus mobilis*, a peritrichously flagellated species. (b) *Heliophilum fasciatum* cell bundles as observed by electron microscopy. (c) Phase-contrast micrograph of endospores from *Heliobacterium gestii*. Most heliobacteria cells are about 1–2 μm in diameter.

their nitrogen fixation activities may benefit rice productivity. A large diversity of heliobacteria have also been found in highly alkaline environments, such as soda lakes and surrounding alkaline soils.

Phototrophic *Acidobacteria*

KEY GENUS: *Chloracidobacterium*

A novel group of anoxygenic phototrophs has been discovered growing in photosynthetic microbial mats of certain thermal springs in Yellowstone National Park (USA). *Chloracidobacterium thermophilum* is a thermophilic oxygen-tolerant anoxygenic phototroph of the phylum *Acidobacteria* (▶ Section 16.21). Like green sulfur bacteria, *C. thermophilum* produces bacteriochlorophyll *a* and *c*, the latter in chlorosomes (Figure 15.21), and uses an FeS-type photosystem. However, unlike green sulfur bacteria, *C. thermophilum* can also grow aerobically, as is true for the aerobic anoxygenic phototrophs (Section 15.5). In terms of its carbon metabolism, *C. thermophilum* is a photoheterotroph that uses short-chain fatty acids as carbon sources, but unlike green sulfur or green nonsulfur bacteria, it is incapable of autotrophy.

Phototrophic *Gemmatimonadetes*

KEY GENUS: *Gemmatimonas*

Another novel group of anoxygenic phototrophs has been discovered in a freshwater lake in the western Gobi desert (part of China and Mongolia). *Gemmatimonas phototrophica* is an aerobic facultative photoheterotroph of the phylum *Gemmatimonadetes*. It gains most of its energy through the aerobic respiration of organic compounds, whether in the light or in the dark. However, in the light, *G. phototrophica* uses photophosphorylation to supplement energy generated by

aerobic respiration. *G. phototrophica* cannot grow as an obligate phototroph, it cannot fix CO₂, and it cannot grow anaerobically. *G. phototrophica* contains a photosynthetic gene cluster that resembles those of aerobic anoxygenic phototrophs (Section 15.5), and it produces bacteriochlorophyll *a* and a Q-type reaction center, both of which are characteristic properties of purple bacteria (◀ Section 14.5). It thus seems likely that *G. phototrophica* acquired its photosynthetic gene cluster and the ability to perform photophosphorylation as the result of an ancient horizontal gene transfer event.

III • Diversity of *Bacteria* Defined by Metabolic Traits

Some microbial metabolisms, such as those where sulfur or iron are oxidized to yield energy, are so characteristic of a specific group of microbes that the metabolism becomes the defining characteristic of the group.

Certain types of microbial metabolism have major impacts on biogeochemical cycling of elements such as nitrogen and sulfur (see Chapter 21). Hence, it is useful to define the diversity of these organisms in terms of their metabolism. All cells must assimilate nitrogen, sulfur, and some metals for growth, and thus all organisms catalyze certain assimilatory reactions. The *Bacteria* and *Archaea*, however, are the only domains containing organisms that can conserve energy from the dissimilative metabolism of inorganic nitrogen, sulfur, and metallic compounds.

In this part of the chapter, we focus on the diversity of microorganisms defined by metabolic traits. We will see that considerable ecological and phylogenetic diversity often exists within any metabolic group and that ecological characteristics often govern the distribution and activity of species within each metabolic group (for example, see Section 15.12). We start our tour of the nitrogen cycle by considering those microbes that reduce atmospheric nitrogen: the nitrogen fixers.

15.9 Diversity of Nitrogen Fixers

KEY GENERA: *Mesorhizobium*, *Desulfovibrio*, *Azotobacter*

Diazotrophs are microorganisms that fix dinitrogen gas (N₂) into NH₃, which can be assimilated as a source of nitrogen for cells. [The term *diazotroph* is derived from a combination of the French *azote*, which means “nitrogen,” the Greek *troph*, which means “eating,” and *di*, which means two. Thus, a diazotroph is an organism that “eats two nitrogens” (N₂)] . Nitrogen fixation is an assimilative process and requires ATP and the enzyme nitrogenase (◀ Section 3.12). Diazotrophs typically fix N₂ only when other forms of N are absent, and nitrogenase expression is inhibited when NH₃ is available to cells. Nitrogenase is irreversibly inhibited by O₂, and this is one

Figure 15.21 Chlorosomes in *Chloracidobacterium thermophilum*, a phototrophic member of the phylum *Acidobacteria*. (a) Electron micrograph of *C. thermophilum* showing chlorosomes. (b) Fluorescence photomicrograph of *C. thermophilum*. The red color is the fluorescence of bacteriochlorophyll *c* present in chlorosomes. A cell of *C. thermophilum* is about 0.8 μm wide.

cause of ecological diversification among diazotrophs; we will see that different organisms have evolved different solutions to protect nitrogenase from O_2 .

Nitrogen fixation is widespread among *Bacteria* and is also found in a few *Archaea*. It is thought to be an ancient process that was present in the last universal common ancestor (◀ Section 13.1). The *nifH* gene encodes the dinitrogenase reductase component of nitrogenase (◀ Section 3.12) and can be used as a measure of diazotroph diversity. More than 30,000 unique *nifH* gene sequences have been described, spanning nine bacterial phyla and one archaeal phylum (Figure 15.1). The phylogenetic distribution of nitrogenase in the tree of life has been influenced strongly by horizontal gene exchange. As a result, the phylogeny of *nifH* is largely inconsistent with the 16S ribosomal RNA gene phylogeny (Figure 15.22). We consider here the diversity of both symbiotic and free-living diazotrophic *Bacteria*.

Symbiotic Diazotrophs

Diazotrophs form several symbiotic relationships with plants, animals, and fungi. These relationships typically consist of a host that provides a hospitable environment, a source of carbon and energy,

and a system for regulating O_2 concentrations, and a microbial symbiont that provides a supply of fixed nitrogen to the host.

The symbiosis between rhizobia and leguminous plants is one of the best-characterized nitrogen-fixing symbiotic associations (▶ Section 23.4). Root-nodule-forming bacteria are *Alphaproteobacteria* (e.g., *Mesorhizobium*, *Bradyrhizobium*, *Sinorhizobium*), *Betaproteobacteria* (e.g., *Burkholderia*), or *Actinobacteria* (e.g., *Frankia*). Other genera of symbiotic diazotrophs are found in association with shipworms (*Teredinibacter*), termite guts (*Treponema*) (▶ Section 23.9), endomycorrhizal fungi (*Glomeribacter*) (▶ Sections 18.12 and 23.5), and several fungi, algae, and plants (*Cyanobacteria*) (▶ Sections 23.1 and 23.4). These different symbioses have evolved independently multiple times as a result of convergent evolution (Figure 15.22).

Free-Living Diazotrophs

Free-living diazotrophs need a mechanism for protecting nitrogenase from oxygen (◀ Section 3.12 and Section 15.3). The simplest solution to this problem is to grow only in anoxic environments. The origin of nitrogen fixation predates the origin of oxygenic photosynthesis, which means the first nitrogen-fixing organisms were free-living anaerobes. Obligately anaerobic free-living diazotrophs are common in anoxic environments including marine and freshwater sediments and microbial mats. Obligately anaerobic free-living diazotrophs are found in the bacterial phyla *Firmicutes* (e.g., *Clostridium*), *Chloroflexi* (e.g., *Oscillochloris*), *Chlorobi* (e.g., *Chlorobium*), *Spirochaetes* (e.g., *Spirochaeta*), and *Proteobacteria* (e.g., *Desulfovibrio*, *Chromatium*, *Rhodobacter*) and in the archaeal phylum *Euryarchaeota* (e.g., *Methanosarcina*). *Desulfovibrio* species occur in anoxic salt marsh sediments dominated by *Spartina* grass, and their N_2 fixation is an important nitrogen source to plants that live in this ecosystem.

Other simple mechanisms for protecting nitrogenase from oxygen include fixing N_2 only at times when oxygen is absent or present in low concentration. For example, facultative aerobes will often fix N_2 only while growing anaerobically (e.g., *Klebsiella*). Some aerobic nitrogen-fixers are *microaerophiles*; these organisms fix nitrogen only in environments where oxygen is present at low concentration (typically less than 2%). However, some organisms have evolved more complex mechanisms for protecting nitrogenase from oxygen and are able to grow in the presence of air.

Obligately aerobic free-living diazotrophs include the *Cyanobacteria* (which have evolved a variety of mechanisms of protecting nitrogenase from oxygen, see Section 15.3) and several unicellular free-living chemoorganotrophic bacteria. Obligately aerobic free-living diazotrophs include *Azotobacter*, *Azospirillum*, and *Beijerinckia*. *Azotobacter* cells are large rods or cocci with diameters of 2–4 μm or more. When they are growing on N_2 as a nitrogen source, extensive capsules or slime layers are typically produced (Figure 15.23 and ◀ Figures 2.16 and 3.29a, b). It is thought that the high respiratory rate characteristic of *Azotobacter* cells and the abundant capsular slime they produce help protect nitrogenase from O_2 . *Azotobacter* is able to grow on many different carbohydrates, alcohols, and organic acids, and metabolism is strictly oxidative.

Azotobacter can form resting structures called *cysts* (Figure 15.24b). Like bacterial endospores, *Azotobacter* cysts show negligible endogenous respiration and are resistant to desiccation, mechanical disintegration,

Figure 15.22 Relationships among diazotrophic (nitrogen-fixing) bacteria as inferred from 16S ribosomal RNA gene sequences and *NifH* amino acid sequences. Branches in each tree are colored to indicate phyla. The dashed lines indicate branches shared between the two trees. The incongruence between the two trees has resulted from multiple horizontal transfer events of the *nifH* gene. Red text denotes obligate anaerobes and underlined text indicates species that form symbioses with *Eukarya*.

and ultraviolet and ionizing radiation. In contrast to endospores, however, cysts are not very heat resistant, and they are not completely dormant because they rapidly oxidize carbon sources if supplied.

Azotobacter and Alternative Nitrogenases

We considered the important process of biological N_2 fixation in Section 3.12 and discussed the central importance of the metals

(a)

(b)

molybdenum (Mo) and iron (Fe) to the enzyme nitrogenase. The species *Azotobacter chroococcum* was the first nitrogen-fixing bacterium shown to grow on N_2 in the absence of molybdenum. This is because either of two “alternative nitrogenases” are formed when Mo limitation prevents the MoFe nitrogenase from being synthesized. These nitrogenases are less efficient than the MoFe nitrogenase and contain either vanadium (V) or Fe in place of Mo. The three different types of nitrogenase (MoFe, VFe, and FeFe) are encoded by paralogous genes and likely arose as the result of gene duplications (◀ Section 13.8). Subsequent investigations of other nitrogen-fixing bacteria have shown that these genetically distinct “backup” nitrogenases are widely distributed among nitrogen-fixing microbes, in particular in the *Cyanobacteria* and *Archaea*.

Check Your Understanding

- What mechanisms do free-living diazotrophs use to protect nitrogenase from oxygen?
- Where might you expect to find nitrogen-fixing bacteria?

15.10 Diversity of Nitrifiers and Denitrifiers

Microorganisms that grow by the anaerobic respiration of inorganic nitrogen (NO_3^- , NO_2^-) to the gaseous products NO , N_2O , and N_2 are called **denitrifiers** (◀ Section 14.11). These organisms are typically facultative aerobes and chemoorganotrophs that use organic carbon as both carbon source and electron donor.

Microorganisms able to grow chemolithotrophically at the expense of reduced inorganic nitrogen compounds (NH_3 , NO_2^-) are called **nitrifiers** (Figure 15.25; ▶ Section 14.11). These organisms are typically obligate aerobes that can also grow autotrophically; most species fix CO_2 by the Calvin cycle. A few species have also been shown to grow mixotrophically by assimilating organic carbon in addition to CO_2 .

Physiology of Nitrifying Bacteria and Archaea

Nitrification often results from the sequential activities of two physiological groups of organisms, the *ammonia oxidizers* (which oxidize NH_3 to nitrite, NO_2^-) (Figure 15.25a) and the *nitrite oxidizers*, the actual nitrate-producing microorganisms, which oxidize NO_2^- to NO_3^- (Figure 15.25b). Ammonia oxidizers typically have genus names beginning in *Nitroso-*, whereas genus names of nitrate producers begin with *Nitro-*. However, certain microbes within the genus *Nitrospira* are able to carry out both ammonia oxidation and nitrite oxidation and are therefore able to oxidize ammonia all the way to nitrate.

Many species of nitrifiers have internal membrane stacks (Figure 15.25) that closely resemble the photosynthetic membranes found in their close phylogenetic relatives, the purple phototrophic bacteria (Section 15.4) and the methane-oxidizing (methanotrophic) bacteria (Section 15.15). The membranes are the location of key enzymes in nitrification: *ammonia monooxygenase*, which oxidizes NH_3 to hydroxylamine (NH_2OH), and *nitrite oxidoreductase*, which oxidizes NO_2^- to NO_3^- (▶ Section 14.9).

Enrichment cultures of nitrifying bacteria can be achieved using mineral salts media containing NH_3 or NO_2^- as electron donors and bicarbonate (HCO_3^-) as the sole carbon source. Because these organisms produce very little ATP from their electron donors

(a)

(b)

Figure 15.25 Nitrifying bacteria. (a) Phase-contrast photomicrograph (left) and electron micrograph (right) of the ammonia-oxidizing bacterium *Nitrosococcus oceanii*. A single cell is about 2 μm in diameter. (b) Phase-contrast photomicrograph (left) and electron micrograph (right) of the nitrite-oxidizing bacterium *Nitrobacter winogradskyi*. A cell is about 0.7 μm in diameter. Beneath each panel is the energy-conserving reaction that each organism catalyzes. The distinct internal membranes of each species are sites of key enzymes of nitrification.

(◀ Section 14.9), visible turbidity may not develop in cultures even after extensive nitrification has occurred. An easy means of monitoring growth is thus to assay for the production of NO_2^- (with NH_3 as electron donor) or NO_3^- (with NO_2^- as electron donor).

Nitrifying Bacteria and Archaea: Ammonia Oxidizers

KEY GENERA: *Nitrosomonas*, *Nitrosospira*, *Nitrosopumilus*

Ammonia oxidizers are found in the Betaproteobacteria (e.g., *Nitrosomonas*, *Nitrosospira*, *Nitrosolobus*, *Nitrosovibrio*) and Gammaproteobacteria (*Nitrosococcus*), in the phylum Nitrospirae, and in the archaeal phylum Thaumarchaeota (*Nitrosopumilus*, *Nitrosocaldus*, *Nitrosoarchaeum*, *Nitrososphaera*).

Ammonia oxidizers are widespread in soil and water. Bacterial ammonia-oxidizers are present in highest numbers in habitats where NH_3 is abundant, such as sites with extensive protein decomposition (ammonification), and also in sewage treatment facilities (▶ Sections 22.6 and 22.7). Nitrifying bacteria develop especially well in lakes and streams that receive inputs of sewage or other wastewaters because these are frequently high in NH_3 . *Nitrosomonas* is often observed in the activated sludge present in aerobic wastewater treatment facilities. Bacterial ammonia-oxidizers are also common in soils (e.g., *Nitrosospira*, *Nitrosovibrio*) and in the oceans (e.g., *Nitrosococcus*).

Archaeal ammonia-oxidizers (*Thaumarchaeota*, ▶ Section 17.5) appear to be most common in habitats where NH_3 is present in low concentration. These organisms are thought to be the dominant ammonia-oxidizers in the oceans where ammonia levels are very low (▶ Sections 20.10 and 20.12). Archaeal ammonia-oxidizers are also common in soils, and in some soils they outnumber bacterial ammonia-oxidizers by several orders of magnitude. The availability of NH_3 relative to NH_4^+ declines with pH (the substrate for the enzyme that oxidizes ammonia, ammonia monooxygenase, is NH_3 , not NH_4^+) and thus acid soils (pH < 6.5), which are common, may favor organisms able to grow at low NH_3 concentration.

Nitrifying Bacteria: Nitrite Oxidizers

KEY GENERA: *Nitrospira*, *Nitrobacter*

Nitrite oxidizers are found in the classes Alpha- (*Nitrobacter*), Beta- (*Nitrotoga*), Gamma- (*Nitrococcus*), and Deltaproteobacteria (*Nitrospina*), as well as in the phylum Nitrospirae (genus *Nitrospira*) (▶ Section 16.21).

Like nitrite-oxidizing Proteobacteria, *Nitrospira* oxidizes nitrite (NO_2^-) to nitrate (NO_3^-) and grows autotrophically (Figure 15.26). However, *Nitrospira* lacks the extensive internal membranes found in species of nitrifying Proteobacteria. Nevertheless, *Nitrospira* inhabits many of the same environments as nitrite-oxidizing Proteobacteria such as *Nitrobacter*, so it has been suggested that its capacity for NO_2^- oxidation may have been acquired by horizontal gene flow from nitrifying Proteobacteria (or vice versa). As we know, this mechanism for acquiring physiological traits has been widely exploited in the bacterial world (Chapter 9 and ◀ Section 13.9). However, environmental surveys for the presence of nitrifying bacteria in nature have shown *Nitrospira* to be much more abundant than *Nitrobacter*; thus most of the NO_2^- oxidized in natural environments is probably due to the activities of *Nitrospira*.

Denitrifying Bacteria and Archaea

KEY GENERA: *Paracoccus*, *Pseudomonas*

Denitrifiers are capable of growth by the anaerobic respiration of NO_3^- or NO_2^- to the gaseous products NO , N_2O , and N_2 (◀ Section 14.11). Nearly all denitrifiers are chemoorganotrophs that use organic carbon as both carbon source and electron donor. Exceptions include the denitrifying sulfur-oxidizers discussed in Section 15.12. Denitrifiers are typically facultative aerobes, and in nearly all cases they will grow preferentially as aerobes if O_2 is present. Denitrifiers are of great importance in agricultural soils where they cause the loss of nitrogen fertilizers and the production of N_2O , which is a dominant component of greenhouse gases produced by agricultural soils (▶ Section 21.9).

Denitrifiers are phylogenetically and metabolically diverse and include two archaeal phyla (▶ Section 17.10) and six bacterial phyla, including five classes of Proteobacteria (Figure 15.1). One of the best-characterized denitrifiers is *Paracoccus denitrificans* (Alpha-proteobacteria). Denitrification of NO_3^- to N_2 requires several key enzymatic steps (◀ Section 14.11), and the genes that encode these enzymes are present throughout the tree of life, indicating the strong influence of horizontal gene exchange. However, many nitrate reducers possess only part of the denitrification pathway and are thus unable to reduce NO_3^- completely to N_2 , producing final products such as NO_2^- , NO , or N_2O .

(a)

(b)

Figure 15.26 Nitrifying bacteria. *Nitrospira* are a genus of nitrifying bacteria often found in biofilms and aggregates. The cell aggregates shown were obtained from activated sludge in a wastewater treatment facility. (a) Multiple cell aggregates (about 100 μm in diameter and $>10^6$ cells each) containing “*Candidatus Nitrospira inopinata*” (yellow), a species capable of completely oxidizing ammonia to nitrite. The biofilm was imaged by confocal laser microscopy using a phylogenetic stain specific for “*Ca. N. inopinata*” (► Section 19.5). (b) A single aggregate of *Nitrospira* cells. Individual cells are curved (arrows) and group into tetrads, which then cluster together to form the larger aggregate. A single cell of *Nitrospira* is about $0.3 \times 1\text{--}2 \mu\text{m}$.

15.11 Dissimilative Sulfur- and Sulfate-Reducers

Sulfur metabolism may have fueled the earliest forms of life on our planet (◀ Section 13.1 and Figure 13.5), and the sulfur cycle (► Section 21.4) continues to support an enormous diversity of microorganisms today. In this section, we consider the diversity of organisms capable of *dissimilative sulfur metabolism*; that is, organisms that conserve energy through the oxidation or reduction of sulfur compounds (◀ Sections 14.7 and 14.12).

The remarkable diversity of *Bacteria* and *Archaea* capable of dissimilative sulfur metabolism is in part a function of the chemical diversity in which sulfur occurs in the biosphere. Sulfur has eight oxidation states that range from its most oxidized form, sulfate (SO_4^{2-} , oxidation state of +6), to thiosulfate ($\text{S}_2\text{O}_3^{2-}$, oxidation state of +2), to elemental sulfur (S^0 , oxidation state of 0), and finally to hydrogen sulfide (H_2S , oxidation state of -2), its most reduced form. In addition, sulfur compounds can take on diverse chemical forms including inorganic sulfur compounds, organosulfur compounds, and metal sulfides.

Dissimilative Sulfate-Reducers

KEY GENERA: *Desulfovibrio*, *Desulfobacter*

Dissimilative sulfate-reducers gain energy by coupling the oxidation of H_2 or organic compounds to the reduction of SO_4^{2-}

(anaerobic respiration, ◀ Section 14.12). The more than 30 known genera of sulfate reducers are found across five phyla of *Bacteria* and *Archaea* (Figure 15.27). Most sulfate reducers reside in the *Deltaproteobacteria*, though sulfate reducers are also found in the *Firmicutes* (e.g., *Desulfotomaculum* and *Desulfosporosinus*), *Thermodesulfobacteria* (e.g., *Thermodesulfobacterium*), and *Nitrospirae* (e.g., *Thermodesulfobivrio*). Sulfate reduction also occurs in *Archaeoglobus*, a genus of the archaeal phylum *Euryarchaeota*.

Physiology of Sulfate-Reducing Bacteria

Sulfate-reducing bacteria are morphologically and biochemically diverse. The biochemistry of sulfate reduction was discussed in Section 14.12, so here we consider some of the more general physiological properties of this group. Sulfate reducers are generally obligate anaerobes, and strict anoxic techniques must be used in their cultivation (Figure 15.28g).

Sulfate reducers use H_2 or organic compounds as electron donors for growth, and the range of organics used is broad. Lactate and pyruvate are almost universally used, and many species also oxidize short-chain alcohols (ethanol, propanol, and butanol) as electron donors. Some species, such as *Desulfosarcina* and *Desulfonema*, grow chemolithotrophically and autotrophically with H_2 as an electron donor, SO_4^{2-} as an electron acceptor, and CO_2 as the sole carbon source. A few sulfate reducers can oxidize hydrocarbons as electron donors (◀ Section 14.24).

There are two physiological types of dissimilative sulfate-reducers, the *complete oxidizers*, which can oxidize acetate and other fatty acids completely to CO_2 , and the *incomplete oxidizers*, which are unable to oxidize acetate to CO_2 . The latter group includes the best studied of the sulfate-reducing bacteria, *Desulfovibrio* (Figure 15.28a), along with *Desulfomonas*, *Desulfotomaculum*, and *Desulfobulbus* (Figure 15.28c). The acetate oxidizers include *Desulfobacter* (Figure 15.28d), *Desulfococcus*, *Desulfosarcina* (Figure 15.28e), and

Figure 15.27 Dissimilative sulfate-reducers. The dendrogram depicts phylogenetic relationships among some genera of sulfate reducers as inferred by analysis of their 16S ribosomal RNA gene sequences. Color shading is used to differentiate the five main phyla that contain genera of sulfate reducers. Colored circles indicate whether species are complete oxidizers, which are able to oxidize acetate to CO₂, or incomplete oxidizers, which cannot oxidize acetate. The physiology of sulfate-reducing bacteria is considered in Section 14.12 and their role in the sulfur cycle in Section 21.4.

Desulfonema (Figure 15.28b), among many others. These bacteria specialize in the oxidation of fatty acids (in particular acetate) to CO₂ and reducing SO₄²⁻ to H₂S. These two physiological groups are not phylogenetically coherent but instead are distributed widely across the phylogeny of sulfate-reducing bacteria (Figure 15.27).

Some sulfate-reducing bacteria can exploit alternative metabolic pathways. In addition to SO_4^{2-} or S^0 , some sulfate reducers can also reduce nitrate and sulfonates (such as isethionate, $\text{HO}-\text{CH}_2-\text{CH}_2-\text{SO}_3^-$). Sulfate-reducing bacteria can also ferment certain organic compounds such as pyruvate. Moreover, although generally obligate anaerobes, a few sulfate-reducing bacteria are quite O_2 -tolerant (primarily strains that coexist with O_2 -producing cyanobacteria in microbial mats). At least one species, *Desulfovibrio oxycyclinae*, can actually grow with O_2 as the electron acceptor under microaerophilic conditions.

Ecology of Sulfate-Reducing Bacteria

Sulfate reducers are widespread in aquatic and terrestrial environments that contain SO_4^{2-} and become anoxic as a result of microbial decomposition. Sulfate reducers are abundant in marine sediments, and the H_2S they generate is responsible for the pungent smell (like that of rotten eggs) often encountered in decaying vegetation near coastal ecosystems. *Desulfotomaculum*, phylogenetically a species of *Firmicutes* (gram-positive *Bacteria*), consists of endospore-forming rods found primarily in soil. Growth and reduction of SO_4^{2-} by *Desulfotomaculum* in certain canned foods leads to a type of spoilage called *sulfide stinker*. Species of *Thermodesulfobacterium*, *Thermodesulfovibrio*, and *Archaeoglobus* (an archaeon) are all thermophilic and found in geothermally heated environments such as hot springs, hydrothermal vents, and oil reserves. The remaining genera of sulfate reducers are indigenous to anoxic marine and freshwater environments and can occasionally be isolated from the mammalian gut.

The enrichment of *Desulfovibrio* species is straightforward in an anoxic lactate-sulfate medium containing ferrous iron (Fe^{2+}). A reducing agent, such as thioglycolate or ascorbate, is required to achieve a low reduction potential (E_0') in the medium. When sulfate-reducing bacteria grow, the H_2S they form combines with the ferrous iron to form black, insoluble ferrous sulfide (Figure 15.28g).

Purification can be accomplished by diluting the culture in molten agar tubes (► Section 19.2 and Figure 19.3*b*). Upon solidification, individual cells of sulfate-reducing bacteria become distributed throughout the agar and grow to form black colonies (Figure 15.28*g*) that can be removed aseptically to yield pure cultures.

Dissimilative Sulfur-Reducers

KEY GENERA: *Desulfuromonas*, *Wolinella*

Here we consider the **dissimilative sulfur-reducers**, microorganisms that are able to use the respiratory reduction of S^0 to conserve energy. Dissimilative sulfur-reducing bacteria can reduce S^0 and other oxidized forms of sulfur (such as SO_3^{2-}) to H_2S but are unable to reduce SO_4^{2-} . There are more than 25 genera of dissimilative sulfur-reducers spread across five bacterial and archaeal phyla (Figure 15.1).

Most sulfur-reducing bacteria are *Proteobacteria*, primarily *Deltaproteobacteria* (e.g., *Desulfuromonas*, *Pelobacter*, *Desulfurella*, *Geobacter*), with some genera residing in the *Epsilonproteobacteria* (e.g., *Wolinella* and *Sulfurospirillum*) and *Gammaproteobacteria* (e.g., *Shewanella* and *Pseudomonas mendocina*). Other sulfur-reducing bacteria are species of *Firmicutes* (e.g., *Desulfitobacterium* and *Ammounifex*), *Aquificae* (e.g., *Desulfurobacterium* and *Aquifex*), *Synergistetes* (e.g., *Dethiosulfovibrio*), *Deinococcus-Thermus* (e.g., *Thermus*) or *Deferribacteres* (e.g., *Geovibrio*). The sulfur-reducing *Archaea*—of which there are many—are all genera of the phylum *Crenarchaeota* (e.g., *Acidianus*, *Pyrodictium*, and *Thermodiscus*).

Physiology and Ecology of Sulfur-Reducing Bacteria

The physiology of sulfur reducers is more diverse than that of sulfate reducers. Most sulfur reducers are obligate anaerobes, but facultatively aerobic species are also common. Sulfur reducers are often able to reduce electron acceptors such as nitrate, ferrous iron, or thiosulfate as alternatives to S^0 . Like sulfate reducers, the physiology of sulfur reducers is characterized by whether they completely oxidize acetate and other fatty acids to CO_2 . Species of *Desulfuromonas* (Figure 15.28f) are complete oxidizers that grow anaerobically by coupling the oxidation of acetate, succinate, ethanol, or propanol to the reduction of S^0 .

(d) *Desulfobacter postgatei*; cell diameter about 1.5 μm . (e) *Desulfosarcina variabilis*; cell diameter about 1.25 μm . (f) *Desulfuromonas acetoxidans*; cell diameter about 0.6 μm . (g) Enrichment culture of sulfate-reducing bacteria. Left, sterile medium; center, a positive enrichment showing black FeS; right, colonies of sulfate-reducing bacteria in a dilution tube (► Section 19.2 and Figure 19.3b). Photos a–d and f are phase-contrast photomicrographs; part e is a differential interference contrast micrograph.

In contrast, *Sulfospirillum* and *Wolinella* are incomplete oxidizers and cannot use acetate as an electron donor. *Sulfospirillum* can reduce S^0 using either H_2 or formate as electron donor.

Dissimilative sulfur-reducing bacteria reside in many of the same habitats as dissimilative sulfate-reducing bacteria and often form

associations with bacteria that oxidize H_2S to S^0 , such as green sulfur bacteria (Section 15.6). The S^0 produced from H_2S oxidation is then reduced back to H_2S during metabolism of the sulfur reducer, completing an anoxic sulfur cycle (► Section 21.4).

Check Your Understanding

- What are the typical electron donors used by dissimilative sulfur-reducers?
- What are the typical electron donors used by dissimilative sulfate-reducers?
- What bacterial phyla are known to contain dissimilative sulfate-reducers?

15.12 Dissimilative Sulfur-Oxidizers

KEY GENERA: *Thiobacillus*, *Achromatium*, *Beggiatoa*

Dissimilative sulfur-oxidizers are **chemolithotrophs** that oxidize reduced sulfur compounds such as H_2S , S^0 , thiosulfate, or thiocyanate (SCN^-) as electron donors in energy conservation, typically with O_2 as electron acceptor. These organisms are common in environments such as marine sediments, sulfur springs, and hydrothermal systems where H_2S produced by sulfate- or sulfur-reducing bacteria (Section 15.11), or abiotically by geothermal reactions, is released into oxygenated waters (Figure 15.29). The sulfur oxidizers are found in three phyla of Bacteria (*Proteobacteria*, *Aquificae*, *Deinococcus-Thermus*) and one of Archaea (*Crenarchaeota*) (Figure 15.1). Most sulfur-oxidizing bacteria are Beta- (*Thiobacillus*), Gamma- (*Achromatium*, *Beggiatoa*), or Epsilonproteobacteria (*Thiovulum*, *Sulfurimonas*).

Physiological Diversity of Sulfur-Oxidizing Bacteria

The morphological and physiological diversity of sulfur oxidizers is significant. Cells can be less than 1 micrometer in diameter (e.g., *Sulfurimonas denitrificans*) or as large as 750 micrometers in diameter (e.g., *Thiomargarita namibiensis*). Most sulfur oxidizers are obligate aerobes; however, species of *Thiomargarita* and *Sulfurimonas* can also reduce NO_3^- in denitrification (◀ Section 14.11 and Section 15.10). Many species oxidize H_2S to elemental sulfur (S^0), which they deposit as either intracellular or extracellular granules for later use as an electron donor (◀ Figure 14.19) if H_2S becomes limiting.

Some sulfur chemolithotrophs are *obligate chemolithotrophs*, locked into a lifestyle of using inorganic instead of organic compounds as electron donors. When growing in this fashion, they are also autotrophs, converting CO_2 into cell material by reactions of the Calvin cycle. **Carboxysomes** are often present in cells of obligate chemolithotrophs (Figure 15.30a). These structures contain high levels of Calvin cycle enzymes and probably increase the rate at which these organisms fix CO_2 (◀ Section 14.2).

Other sulfur chemolithotrophs are *facultative chemolithotrophs*, facultative in the sense that they can grow *either* chemolithotrophically (and thus, also as autotrophs) *or* chemoorganotrophically. Most species of *Beggiatoa* can obtain energy from the oxidation of inorganic sulfur compounds but lack enzymes of the Calvin cycle. They thus require organic compounds as carbon sources. Organisms that use a mix of carbon and energy sources, for example those that simultaneously assimilate carbon from both CO_2 and organic sources, are called **mixotrophs**.

(b)

Figure 15.29 Habitats of sulfur oxidizers. (a) A sulfidic artesian spring in Florida (USA). The outside of the spring is coated with a mat of *Thiobacillus* (see Figure 15.31b). The mat is about 1.5 m in diameter. (b) Hydrothermal chimneys at Cathedral Hill in the Guaymas Basin (Mexico), 2000-m depth. Sulfide-rich waters vent from the chimneys, which are covered by mats composed of orange, white, and yellow cells of *Beggiatoa*.

Thiobacillus and Achromatium

The genus *Thiobacillus* and related genera include several gram-negative, rod-shaped *Betaproteobacteria* (Figure 15.30a) that are the best studied of the sulfur chemolithotrophs. The oxidation of H_2S , S^0 , or thiosulfate by *Thiobacillus* generates sulfuric acid (H_2SO_4), and thus thiobacilli are often acidophilic. One highly acidophilic species, *Acidithiobacillus ferrooxidans*, can also grow chemolithotrophically by the oxidation of Fe^{2+} and is a major biological agent for the oxidation of this metal. Iron pyrite (FeS_2) is a major natural source of ferrous iron as well as of sulfide. The oxidation of FeS_2 , especially in mining operations, can be both beneficial (because leaching of the ore releases the iron from the sulfide mineral) and ecologically disastrous (the environment can become acidic and contaminated with toxic metals such as aluminum, cadmium, and lead) (► Sections 22.1 and 22.2).

Achromatium is a spherical sulfur-oxidizing chemolithotroph that is common in freshwater sediments of neutral pH containing H_2S . Cells of *Achromatium* are large cocci that can have diameters of 10–100 μm (Figure 15.30b). *Achromatium* is a species of *Gammaproteobacteria* and is specifically related to purple sulfur bacteria, such as its phototrophic counterpart *Chromatium* (Section 15.4 and Figure 15.10a). Like *Chromatium*, cells of *Achromatium* store S^0 internally (Figure 15.30b); the granules later disappear as S^0 is oxidized to SO_4^{2-} . Cells of *Achromatium* also store large granules of calcite

(CaCO_3) (Figure 15.30b), possibly as a carbon source (in the form of CO_2) for autotrophic growth. The physiology of chemolithotrophic sulfur-oxidizers is discussed in Section 14.7.

Ecological Diversity and Strategies of Sulfide-Oxidizing Bacteria

Aerobic sulfide-oxidizers provide a case study that demonstrates the degree of ecological diversification that can occur among microbes that share the same basic metabolic features. The chemical oxidation of H_2S to H_2SO_4 is spontaneous and rapid in the presence of O_2 . Hence, aerobic H_2S -oxidizers have evolved diverse ecological strategies that allow them to metabolize two molecules that otherwise react with each other spontaneously. We consider here six different strategies used by aerobic sulfide-oxidizers to cope with the chemical instability of H_2S in the presence of O_2 .

- *Thiobacillus* is a filamentous sulfur chemolithotroph that forms filaments that group together at their ends by way of a holdfast to form cell arrangements called *rosettes* (Figure 15.31). The ecological strategy of *Thiobacillus* is to use its holdfast to position itself in

high-flow environments downstream from a source of H_2S . Such environments are common near sulfur springs and in creeks draining sulfidic salt marshes where abundant H_2S is produced and carried away in waters rich with O_2 (Figure 15.31a). Physiologically, *Thiothrix* is an obligately aerobic mixotroph, and in this and most other respects, it resembles *Beggiatoa*.

- *Beggiatoa* are filamentous, gliding, sulfur-oxidizing bacteria that are usually large in both diameter and length, consisting of many short cells attached end to end (Figure 15.32a). Filaments can flex and twist so that many filaments become intertwined to form a complex tuft. *Beggiatoa* is found primarily in microbial mats, sediments, sulfur springs, and hot springs. The ecological strategy of

Note the abundant elemental sulfur granules in some of the cells. (b) Cells of a large marine *Thioploca* species. Cells contain sulfur granules (yellow) and are about 40–50 μm wide.

Beggiatoa is to use gliding motility to position itself at the point where H_2S and O_2 co-occur in an environment. For example, *Beggiatoa* in microbial mats can move vertically by as much as several centimeters per day in response to cyanobacterial O_2 production, moving up to obtain O_2 when photosynthesis ceases at night and down during the day when cyanobacterial O_2 production at the mat surface causes H_2S to be found deeper in the mat.

- The genus *Thiomargarita* contains some of the largest bacteria yet observed, with diameters that can be as much as 0.75 millimeter (Figure 15.33). *Thiomargarita* is nonmotile, and its ecological strategy is to separate in time the oxidation of H_2S from the reduction of O_2 . To accomplish this, *Thiomargarita* contains a giant vacuole (Figure 15.33b) that it fills with high concentrations of nitrate (NO_3^-). This vacuole can fill almost the entire volume of the cell. Cells live in sulfide-rich marine sediments that are mixed occasionally with O_2 -rich waters, such as that in salt marshes and in ocean upwelling zones. When buried in sediment, cells oxidize H_2S to S^0 anaerobically by reducing NO_3^- stored in the vacuole to ammonium (NH_4^+). They then store the S^0 as intracellular granules (Figure 15.33a). When turbulent waters mix the cells into the water column where H_2S is lacking, they switch to the aerobic oxidation of stored S^0 . The energy they gain from S^0 oxidation is used to refill their vacuole with NO_3^- from the water column so they will be able to survive the next period of anoxia.

Figure 15.33 The giant sulfide-oxidizing bacterium, *Thiomargarita*. (a) *Thiomargarita namibiensis* recovered from the Namibian upwelling (off the Namibian coast, southwest Africa). Cells are about 100 μm in diameter. (b) Dividing cells of vacuole-containing sulfide-oxidizers recovered from the same location. The fluorescence micrograph shows ribosomes of *Thiomargarita* stained with a fluorescent nucleic acid probe. Ribosomes are found in the cytoplasm, which is present as a thin layer along the outer edge of the cells. The cytoplasm is squeezed between the cell wall and the large central vacuole, which appears dark in the image. Cells are about 50 μm wide.

- *Thioploca* are large filamentous bacteria that use a strategy similar to that of *Thiomargarita*. *Thioploca* also have intracellular S^0 granules and large vacuoles filled with NO_3^- (Figure 15.32b). However, filaments of *Thioploca* are motile by gliding and they occur in large sheaths that can be filled with many parallel filaments (Figure 15.32b). Sheaths are arranged vertically in the sediments and filaments glide up and down in the sheaths, going down to anaerobically respire H_2S using stored NO_3^- as electron acceptor and going up to aerobically respire S^0 and to refill their vacuoles with NO_3^- (► Figure 20.10).
- *Thiovulum* are found in freshwater and marine habitats in which sulfide-rich muds interface with oxic zones (Figure 15.34). *Thiovulum* cells are fairly large (10–20 μm) cocci, and when motile, they swim at exceptionally high speed, perhaps the fastest of all known bacteria ($\sim 0.6 \text{ mm/sec}$). The ecological strategy of *Thiovulum* is to actually control the flow of nutrients to cells. *Thiovulum* cells secrete a slime that links cells together in a veil-like structure that can be centimeters in diameter (Figure 15.34a). The veils, composed of many *Thiovulum*

cells (Figure 15.34b), are formed over a source of H_2S . Cells have long flagella that attach to the veil and to solid surfaces. Since the terminal end of the flagellum is attached and immobile, flagellar rotation causes cells to rotate along their flagellar axis (Figure 15.34c). The simultaneous unidirectional rotation of all the *Thiovulum* cells in the veil creates a flow of water through the veil, allowing the cells (Figure 15.34b, d) to generate and regulate the gradients of H_2S and O_2 they require to generate energy (Figure 15.34c).

- The final ecological strategy of sulfur chemolithotrophs is for the organism to form a symbiotic association with a eukaryote. There are diverse symbiotic associations in which the host provides a mechanism for regulating H_2S and O_2 levels and the sulfide-oxidizing symbiont fixes CO_2 and provides a source of carbon and energy to the host. The best example is the tube worm *Riftia*, which contains sulfide-oxidizing endosymbionts and lives at deep-sea hydrothermal vents (► Section 23.11). A variety of other such symbiotic associations are present at hydrothermal vent

Figure 15.34 The sulfide-oxidizing bacterium *Thiovulum*. (a) Photo of a *Thiovulum* veil forming over marine sediment. The veil, composed of many cells within a polysaccharide matrix, appears like a spider web covering the sediment surface. Under the veil, H_2S is released from the sediment. (b) Close-up photograph of *Thiovulum* cells (yellow dots) within their veil. (c) *Thiovulum* cells attach to the sediment with a long holdfast and begin to rotate. The collective rotation of the many cells within the veil cause O_2 -rich water above the veil to be pumped down across the veil. Hence, through collective action, *Thiovulum* cells manipulate their environment to optimize local concentrations of O_2 and H_2S . (d) Transmission electron micrograph of a section from a dividing cell of *Thiovulum*. Arrows point to sulfur (S^0) globules. Single cells of *Thiovulum* are typically 10–20 μm in diameter.

ecosystems, including symbionts living in the gill tissue of the giant clam *Calyptogena magnifica* and on the surface of the yeti crab, which farms sulfide-oxidizing bacteria by waving its claws over sulfide-rich vent fluid. Symbioses involving invertebrates are also common in the sulfide-rich marine sediments of shallow coastal systems. For example, bivalves in the family *Solemyidae* burrow into sulfide-rich sediments and pump sulfide- and oxygen-rich water over gills that contain sulfide-oxidizing bacteria.

From these examples it should be clear how ecological diversity drives bacteria that carry out the same energy metabolism—in this case sulfide oxidation—to best exploit the different environments they inhabit. In each case, the goal of the organism is the same, to obtain the electron donor and acceptor it needs. But also in each case, the strategy to accomplish this is unique and the best fit to both the properties of the organism and the habitat it exploits.

- What are some ecological strategies that sulfur oxidizers use to compete with the spontaneous (chemical) oxidation of H_2S ?

15.13 Dissimilative Iron-Reducers

KEY GENERA: *Geobacter*, *Shewanella*

Dissimilative iron-reducers couple the reduction of oxidized metals or metalloids to cellular growth. These organisms need to overcome the fundamental obstacle of using an insoluble solid material as an electron acceptor in respiration (◀ Section 14.13). A variety of microorganisms are able to enzymatically reduce metals as a consequence of either fermentation reactions or sulfur or sulfate reduction, but such organisms do not conserve energy from metal reduction. In contrast, dissimilative iron-reducers carry out metal respiration by coupling the oxidation of H_2 or organic compounds to the reduction of ferric iron (Fe^{3+}) (Figure 15.35a) or manganese (Mn^{6+}).

Dissimilative iron-reducers are phylogenetically diverse (Figure 15.1). Iron-reducing bacterial genera are found in the *Proteobacteria* (*Geobacter*, *Shewanella*), *Acidobacteria* (*Geothrix*), *Deferribacteres* (*Geovibrio*), *Deinococcus-Thermus* (*Thermus*), *Thermotogae* (*Thermotoga*), and *Firmicutes* (*Bacillus*, *Thiobacillus*), while archaeal genera are found in the *Crenarchaeota* (*Pyrobaculum*). Iron respiration likely evolved early in the history of life, and its wide distribution may be due to its presence in the universal ancestor coupled with subsequent gene loss in some lineages and horizontal gene transfer to others.

Physiology

Dissimilative iron-reducers specialize in using insoluble external electron acceptors, and these organisms are typically extremely versatile at anaerobic respiration. Dissimilative iron-reducers are unusual in that they possess outer membrane cytochromes that facilitate electron transfer with insoluble minerals (◀ Figure 14.31). Most species are able to use either iron oxides or manganese oxides as electron acceptors, and various species are also able to use nitrate, fumarate, and oxidized inorganic sulfur, cobalt, chromium, uranium, tellurium, selenium, arsenic, and humic compounds (◀ Section 14.13). Most genera of iron-reducing bacteria are obligate anaerobes, but some, such as

Figure 15.35 The dissimilative iron-reducing bacterium *Geobacter*. (a) The uninoculated tube (left) contains an anoxic medium that includes acetate and ferrihydrite, a poorly magnetic iron oxide. Following growth of *Geobacter* (right tube) the ferrihydrite is reduced to magnetite, which is magnetic. (b) Transmission electron micrograph of *Geobacter sulfurreducens* showing flagella and pili (◀ Figure 14.31). The cell is about $0.7 \times 3.5 \mu\text{m}$. (c) Transmission electron micrograph of *G. sulfurreducens* showing immunogold labeling of cytochrome OmcS on the pili (arrow).

Shewanella and relatives, are facultative aerobes. Electron donors are typically organic compounds such as fatty acids, alcohols, sugars, and in certain cases, even aromatic compounds. Many species are also able to use H_2 as an electron donor, but they are generally unable to grow autotrophically, requiring a source of organic carbon to support growth.

The family *Geobacteraceae* in the *Deltaproteobacteria* contains four genera of dissimilative iron-reducing bacteria (*Geobacter*, *Desulfuromonas*, *Desulfuromusa*, *Pelobacter*) that aptly demonstrate the physiological diversity of the obligately anaerobic metal reducers. *Geobacter*, *Desulfuromonas*, and *Desulfuromusa* can all use acetate as an electron donor as well as a diversity of other small organics, and they oxidize these substrates completely to CO_2 . These genera typically specialize in anaerobic respiration. *Geobacter* in particular can use a wide range of electron donors and acceptors. *Geobacter* produce pili (Figure 15.35b) that contain cytochromes (Figure 15.35c), and these pili facilitate electron transfer to the surface of iron oxide minerals. *Pelobacter*, in contrast, are primarily fermentative organisms having a more limited respiratory capacity. For example, *Pelobacter carbinolicus* can only use lactate as the electron donor and can only use ferric iron or S^0 as the electron acceptors. *Pelobacter* species are unable to oxidize their carbon substrates completely to CO_2 .

Shewanella and its relatives *Ferrimonas* and *Aeromonas* in the *Gammaproteobacteria* are facultative aerobes and will grow aerobically when O_2 is available. *Shewanella* are able to use a wide diversity of electron donors and acceptors in addition to ferric iron and manganese. However, like *Pelobacter* species, they are unable to oxidize their carbon substrates completely to CO_2 and are unable to oxidize acetate as an electron donor for anaerobic respiration.

Ecology

Dissimilative iron-reducers are common in anoxic freshwater and marine sediments. These organisms are thought to play an important role in organic matter oxidation in many anoxic habitats. Dissimilative iron-reducers are also common in shallow aquifers as well as in the deep subsurface environment (► Section 20.8). In addition, several thermophilic and hyperthermophilic iron-reducing species are known (e.g., *Thermus*, *Thermotoga*) and are often found in hot springs and other geothermally heated systems, including the deep subsurface.

Check Your Understanding

- In what phylogenetic groups are *Geobacter* and *Shewanella* found?
- Which genera of dissimilative iron-reducers contain facultative aerobes?

15.14 Dissimilative Iron-Oxidizers

KEY GENERA: *Acidithiobacillus*, *Gallionella*

The ability to couple the oxidation of ferrous iron (Fe^{2+}) to cell growth is widespread in the tree of life and thought to be a trait that evolved early in Earth's history. Genera capable of using ferrous iron as an electron donor to support growth are spread across five bacterial and two archaeal phyla (Figure 15.1).

Aerobic iron-oxidizer diversity and distribution are influenced strongly by pH and O_2 . Ferrous iron oxidizes spontaneously to form insoluble precipitates in the presence of O_2 at neutral to alkaline pH (pH > 7) but is stable either under anoxic conditions or aerobically at acidic pH (pH < 4). Iron oxidizers can be divided into four functional groups on the basis of their physiology: acidophilic aerobic iron-oxidizers, neutrophilic aerobic iron-oxidizers, anaerobic chemotrophic iron-oxidizers, and anaerobic phototrophic iron-oxidizers.

Acidophilic Aerobic Iron-Oxidizing Bacteria

The growth of iron-oxidizing bacteria is favored in iron-rich acidic environments where soluble ferrous iron is present. Aerobic iron-oxidizers are often abundant in acid mine drainage generated from abandoned coal or iron mines or from mine tailings (► Sections 22.1 and 22.2). Acidophilic aerobic iron-oxidizers also inhabit iron-rich acidic springs in volcanic areas. In these environments, sulfur is often present along with ferrous iron, and many acidophilic aerobic iron-oxidizers are able to oxidize both elemental sulfur and ferrous iron. Species can be either autotrophic or heterotrophic, and commonly observed genera include *Acidithiobacillus* (*Gammaproteobacteria*), *Leptospirillum* (*Nitrospirae*), and *Ferropasma* (*Euryarchaeota*). Other acidophilic aerobic iron-oxidizers can be found in the *Actinobacteria* and *Firmicutes*.

Neutrophilic Aerobic Iron-Oxidizing Bacteria

Neutrophilic aerobic iron-oxidizers are organisms adapted to a specialized niche (◄ Section 14.8 and see Microbiology Now on page 514). This is because ferrous iron is relatively insoluble at neutral pH and its chemical oxidation is spontaneous and rapid in the presence of air. Furthermore, at neutral pH, iron oxidation at the cell surface causes the formation of an iron oxide crust that can effectively entomb growing cells. Neutrophilic aerobic iron-oxidizers therefore thrive where iron-rich anoxic waters are exposed to air. Such habitats are common

near wetlands or soils where anoxic groundwater forms a spring, but iron oxidizers also inhabit the rhizosphere of wetland plants and certain submarine hydrothermal systems.

Few genera of neutrophilic aerobic iron-oxidizers have been described and they all belong to the *Proteobacteria*. Those species found in freshwater habitats belong to a set of closely related genera in the *Betaproteobacteria*, while species found in marine habitats belong to the *Zetaproteobacteria*. The metabolism of these organisms is fairly narrow. Species are typically microaerophiles and obligate chemolithotrophs, though in certain cases mixotrophy has been observed. The genera *Leptothrix* and *Sphaerotilus* are exceptions (Section 15.19). *Leptothrix* and *Sphaerotilus* are common in freshwater environments containing neutrophilic aerobic iron-oxidizers. They catalyze the oxidation of both iron and manganese but do not appear to conserve energy from these reactions, conserving energy instead from the oxidation of organic matter.

Characteristic species of neutrophilic aerobic iron-oxidizers are found in the genus *Gallionella* (freshwater) and the marine genus *Mariprofundus* (marine) (► Section 21.6 and Figure 21.19). Species of *Gallionella* and *Mariprofundus* each form a twisted stalklike structure containing $\text{Fe}(\text{OH})_3$ from the oxidation of ferrous iron (Figure 15.36). The iron-encrusted stalk contains an organic matrix on which $\text{Fe}(\text{OH})_3$ accumulates as it is excreted from the cell surface. Stalk formation is presumably an adaptation that prevents cells from becoming entombed in an iron oxide crust.

Figure 15.36 The neutrophilic ferrous iron-oxidizer *Gallionella ferruginea*, from an iron seep near Ithaca, New York. (a) Photomicrograph of two bean-shaped cells with stalks that combine to form one twisted mass. (b) Transmission electron micrograph of a thin section of a *Gallionella* cell with stalk. Cells are about 0.6 μm wide.

Gallionella is common in the waters draining bogs, iron springs, and other habitats where ferrous iron is present. *Mariprofundus* was first isolated from Lō'ihi Seamount, a submarine volcano near Hawaii (► Section 21.5 and Figure 21.18). *Gallionella* and *Mariprofundus* are both autotrophic chemolithotrophs containing enzymes of the Calvin cycle (◄ Sections 3.12 and 14.2).

Anaerobic Iron-Oxidizing Bacteria

Anaerobic ferrous iron oxidation can be mediated by both chemotrophic and phototrophic bacteria. These groups are common in anoxic sediments and wetlands. Anoxic conditions promote the solubility of ferrous iron across a wide range of pH and so, unlike the aerobic iron-oxidizing bacteria, growth of anaerobic iron-oxidizers is not strictly limited to neutral pH. These groups contain organisms that are metabolically diverse and able to grow by using a variety of different electron donors and acceptors.

Phototrophic iron oxidation occurs in select species of purple nonsulfur bacteria of the *Alphaproteobacteria* (e.g., *Rhodospseudomonas palustris*), select species of purple sulfur bacteria of the *Gammaproteobacteria* (◄ Figure 14.23), and select species of green sulfur bacteria found in the *Chlorobi* (*Chlorobium ferrooxidans*). In all cases ferrous iron is one of several compounds that these organisms can use as an electron donor in photosynthesis.

Anaerobic chemotrophic iron-oxidizers couple the oxidation of ferrous iron to nitrate reduction, producing either NO_2^- or nitrogen gases (denitrification). These organisms are *Alpha*-, *Beta*-, *Gamma*-, or *Deltaproteobacteria*, and most are also able to use various organic electron donors in nitrate reduction; many can also grow aerobically. The bacterial genera *Acidovorax*, *Aquabacterium*, and *Marinobacter* all contain anaerobic iron-oxidizers. While most species are mixotrophs when growing with ferrous iron as electron donor, species such as *Marinobacter aquaeolei* and *Thiobacillus denitrificans* are able to grow autotrophically as iron-oxidizing chemolithotrophs.

Check Your Understanding

- What habitat characteristics govern the diversity and distribution of iron oxidizers?
- How do aerobic neutrophilic iron-oxidizers keep their cells from becoming entombed in a crust of iron?

15.15 Methanotrophs and Methylotrophs

Methylotrophs are organisms that grow using organic compounds lacking C—C bonds as electron donors in energy metabolism and as carbon sources. Methylotrophy occurs in the bacterial phyla *Proteobacteria*, *Firmicutes*, *Actinobacteria*, *Bacteroidetes*, *Verrucomicrobia*, and in the archaeal phylum *Euryarchaeota* (Figure 15.1). **Methanotrophs** are a subset of methylotrophs defined by their ability to use methane as a substrate for growth (◄ Section 14.16).

Aerobic methylotrophs are common in soil and aquatic environments where O_2 is present. Anaerobic methylotrophs are common in anoxic environments, particularly in marine sediments. Many anaerobic methylotrophs are methanogenic *Archaea*. In addition, a consortium of methanogenic *Archaea* and sulfate-reducing bacteria combine to oxidize methane from gas hydrates found in deep-sea sediments (◄ Section 14.16 and Figure 14.41). We consider here only the aerobic methylotrophs.

Aerobic Facultative Methylotrophs

KEY GENERA: *Hyphomicrobium*, *Methylobacterium*

Aerobic facultative methylotrophs are unable to use methane but can use many other methylated compounds. They are species of *Alpha*-, *Beta*-, and *Gammaproteobacteria*, *Actinobacteria*, and *Firmicutes*. Facultative methylotrophs are metabolically diverse and, in addition to methylated substrates, most species can grow aerobically using other organic compounds, such as organic acids, ethanol, and sugars. When growing as methylotrophs, most species can grow aerobically with methanol and some can also metabolize methylated amines, methylated sulfur compounds, and halomethanes. Most are obligate aerobes, though some species are capable of denitrification.

The genus *Hyphomicrobium* provides an example of the metabolic versatility of the aerobic facultative methylotrophs. Certain species of *Hyphomicrobium* can grow as aerobic methylotrophs using methanol, methylamine, or dimethyl sulfide. Species of *Hyphomicrobium* can also grow as anaerobic methylotrophs using methanol as an electron donor coupled to denitrification. Finally, *Hyphomicrobium* can grow aerobically on a range of C_2 and C_4 compounds.

Aerobic Methanotrophs

KEY GENERA: *Methylomonas*, *Methylosinus*

Aerobic methanotrophs are methylotrophs that can use methane as an electron donor and typically can use it as a carbon source as well. **Table 15.1** gives a taxonomic overview of the methanotrophs. Most methanotrophs are *Proteobacteria* and are classified into two major groups based on their internal cell structure, phylogeny, and carbon assimilation pathway. *Type I methanotrophs* assimilate one-carbon compounds via the ribulose monophosphate cycle and are *Gammaproteobacteria*. By contrast, *type II methanotrophs* assimilate C_1 intermediates via the serine pathway and are *Alphaproteobacteria* (Table 15.1). We discussed the biochemical details of these pathways in Section 14.16.

TABLE 15.1 Some characteristics of methanotrophic Bacteria

^bSee Figure 14.40.

^cAcidophiles. For the properties of *Verrucomicrobiaceae*, see Section 16.17.

Most methanotrophs are metabolically specialized for aerobic growth on methane, though some can grow on either methane or methanol. Methanotrophs are typically obligate methylotrophs; however, the methanotrophic genus *Methylocella* contains species that can also grow on acetate or organic acids such as pyruvate and succinate.

In addition to the proteobacterial methanotrophs described above, the phylum *Verrucomicrobia* contains the bacterium *Methylocidiphilum*. Genome analysis has shown that species of *Methylocidiphilum* lack key enzymes of both the ribulose monophosphate and serine pathways. Instead, *Methylocidiphilum* uses the Calvin cycle to assimilate carbon from CO₂.

Physiology

Methanotrophs possess a key enzyme, *methane monooxygenase*, that catalyzes the incorporation of an atom of oxygen from O₂ into CH₄, forming methanol (CH₃OH, ◀ Section 14.16). The requirement for O₂ as a reactant in the initial oxygenation of CH₄ explains why these methanotrophs are obligate aerobes. Methane monooxygenase is located in extensive internal membrane systems that are the site of methane oxidation. Membranes in type I methanotrophs are arranged as bundles of disk-shaped vesicles distributed throughout the cell (Figure 15.37*b*). Type II species possess paired membranes running along the periphery of the cell (Figure 15.37*a*). Verrucomicrobial methanotrophs possess membrane vesicles. Methylotrophs unable to use methane lack these internal membrane arrays.

Methanotrophs are virtually unique among bacteria in possessing relatively large amounts of sterols. Sterols are rigid planar molecules found in the cytoplasmic and other membranes of eukaryotes but are absent from most bacteria. Sterols may be an essential part of the complex internal membrane system for methane oxidation (see Figure 15.37). The only other group of bacteria in which sterols are widely distributed is the mycoplasmas, bacteria that lack cell walls and thus probably require a tougher cytoplasmic membrane

(▶ Section 16.9). Many methylotrophs contain various carotenoid pigments and high levels of cytochromes in their membranes, and these features often render colonies of aerobic methylotrophs pink.

Ecology

Aerobic methylotrophs are found in the open ocean, in soils, in association with plant roots and leaf surfaces, and at the oxic interface of many anoxic environments. Methanol is produced during the breakdown of plant pectin and this is likely an important substrate for methylotrophs in terrestrial ecosystems. In addition, soils contain aerobic methanotrophs that consume atmospheric methane and are an important biological sink for atmospheric methane. Aerobic methanotrophs are also common at the oxic interface of anoxic environments found in lakes, sediments, and wetlands where methanogens provide a constant source of methane. These methanotrophs play an important role in the global carbon cycle by oxidizing CH₄ and converting it into cell material and CO₂ before it reaches the atmosphere (CH₄ is a strong greenhouse gas).

Methanotrophs also form a variety of symbioses with eukaryotic organisms. For example, some marine mussels live in the vicinity of hydrocarbon seeps on the seafloor, places where CH₄ is released in substantial amounts. Methanotrophic symbionts reside within the animal's gill tissue (Figure 15.38), which ensures effective gas exchange with seawater. Assimilated CH₄ is distributed throughout the animal by the excretion of organic compounds by the methanotrophs. These methanotrophic symbioses are therefore conceptually similar to those that develop between sulfide-oxidizing chemolithotrophs and hydrothermal vent tube worms and giant clams (▶ Section 23.11).

Methyloirabilis oxyfera is a methanotroph isolated from anoxic waters in the Black Sea, and it was the first isolate obtained from the unique bacterial phylum NC-10. *M. oxyfera* is an obligate anaerobe; however, it uses the O₂-dependent enzyme of aerobic methanotrophs (methane monooxygenase) to oxidize methane to CO₂. *M. oxyfera* accomplishes this by reducing nitrite to nitric oxide (NO),

(a)

(b)

which is then dismutated to N_2 and O_2 ($2\text{NO} \rightarrow \text{N}_2 + \text{O}_2$). The O_2 produced by this pathway is then consumed by methane monooxygenase during the oxidation of CH_4 (◀ Section 14.16). Like the methanotroph *Methylococcus*, *M. oxyfera* assimilates C_1 units as CO_2 , probably by the Calvin cycle.

IV • Morphologically and Ecologically Distinctive Bacteria

Some Bacteria are so morphologically distinct that they can be instantly recognized, even in natural samples. Other Bacteria display some unique behavioral property—such as predation or motility controlled by magnetic particles—that sets them apart from all other microbes in an ecological sense.

Many microbes have distinctive lifestyles or morphological characteristics that differentiate them from other organisms. These traits are often associated with specific ecological properties. For example, some chemoorganotrophs obtain their carbon and energy by consuming other organisms. We begin this section by discussing microbial predators.

15.16 Microbial Predators

KEY GENERA: *Bdellovibrio*, *Myxococcus*

Some bacteria are predators that consume other bacteria. Known bacterial predators reside among several classes of *Proteobacteria* and in the *Bacteroidetes*, *Chloroflexi*, and *Melainabacteria*. Several different methods of predation have been observed. Some predators, such as *Vampirococcus* (phylogeny unknown), *Micavibrio* (*Alphaproteobacteria*), and the green algal predator *Vampirotubus* (*Melainabacteria*) are *epibiotic predators*; they attach to the surface of their prey and acquire nutrients from its cytoplasm or periplasm. Other predators, such as *Daptobacter* (*Epsilonproteobacteria*), are *cytoplasmic predators*, as they invade their host cells and replicate in the cytoplasm, consuming their prey from the inside out. *Bdellovibrio* have a similar lifestyle as *periplasmic predators*; they invade and replicate within the periplasmic space of their prey cells. Finally, predators such as *Lysobacter* (*Gammaproteobacteria*) and *Myxococcus* (*Deltaproteobacteria*) are *social predators*. These gliding bacteria use swarming behavior to find prey, which they lyse and feed upon collectively. *Bdellovibrio* and *Myxococcus* are the most thoroughly described genera of bacterial predators.

Bdellovibrio

Bdellovibrio are small, highly motile and curved bacteria that prey on other bacteria, using the cytoplasmic constituents of their hosts as nutrients (*bdello* is a prefix meaning “leech”). After attachment of a *Bdellovibrio* cell to its prey, the predator penetrates the cell wall of the prey and replicates in the periplasmic space, eventually forming a spherical structure called a *bdelloplast*. Two stages of penetration are shown in electron micrographs in Figure 15.39 and diagrammatically in Figure 15.40b. A wide variety of gram-negative prey bacteria can be attacked by *Bdellovibrio*, but gram-positive cells are not attacked.

Bdellovibrio is an obligate aerobe, obtaining its energy from the oxidation of amino acids and acetate. In addition, *Bdellovibrio* assimilates nucleotides, fatty acids, peptides, and even some intact proteins directly

Figure 15.39 Attack on a prey cell by *Bdellovibrio*. Thin-section electron micrographs of *Bdellovibrio* attacking a cell of *Delftia acidovorans*. (a) Entry of the predator cell. (b) *Bdellovibrio* cell inside the host. The *Bdellovibrio* cell is enclosed in the bdelloplast and replicates in the periplasmic space. A *Bdellovibrio* cell measures about 0.3 μm in diameter.

(a)

Figure 15.40 Developmental cycle of the bacterial predator *Bdellovibrio bacteriovorus*. (a) Electron micrograph of a cell of *Bdellovibrio bacteriovorus*; note the thick flagellum. A cell is $0.3\ \mu\text{m}$ wide. (b) Events in predation. Following primary contact with a gram-negative bacterium, the highly motile *Bdellovibrio* cell attaches to and penetrates into the prey periplasmic space. Once inside the periplasmic space, *Bdellovibrio* cells elongate, and within 4 h progeny cells are released. The number of progeny cells released varies with the size of the prey; 5–6 bdellovibrios are released from *Escherichia coli* and 20–30 for a larger prey cell, such as *Aquaspirillum*.

from its host without first hydrolyzing them. Prey-independent derivatives of *Bdellovibrio* can be isolated and grown on complex media, however, showing that predation is not an obligatory lifestyle.

Phylogenetically, bdellovibrios are *Deltaproteobacteria*, and they are widespread in aquatic habitats. Procedures for their isolation are similar to those used to isolate bacterial viruses (Section 5.3). Prey bacteria are spread on the surface of an agar plate, forming a lawn, and the surface is inoculated with a small amount of soil suspension that has been filtered through a membrane filter; the filter retains most bacteria but allows the small *Bdellovibrio* cells to pass. On incubation of the agar plate, plaques analogous to bacteriophage plaques

(Figure 5.10b) are formed at locations where *Bdellovibrio* cells are multiplying. Pure cultures of *Bdellovibrio* can then be isolated from these plaques. *Bdellovibrio* are widely distributed, as cultures have been obtained from many soils and from sewage.

Myxobacteria

Myxobacteria exhibit the most complex behavioral patterns of all known bacteria. The life cycle of myxobacteria results in the formation of multicellular structures called *fruiting bodies*. The fruiting bodies are often strikingly colored and morphologically elaborate (Figure 15.41), and these can often be seen with a hand lens on moist pieces of decaying wood or plant material. The fruiting myxobacteria are classified on morphological grounds using characteristics of the vegetative cells, the myxospores, and fruiting body structure.

The life cycle of a typical myxobacterium is shown in Figure 15.42. The vegetative cells of the myxobacteria are simple, nonflagellated, gram-negative rods (Figure 15.42) that glide across surfaces and obtain their nutrients primarily by using extracellular enzymes to lyse other bacteria and use the released nutrients. A vegetative cell

Figure 15.42 Life cycle of *Myxococcus*. Dormant myxospores germinate under favorable conditions to yield vegetative cells. Vegetative cells exhibit adventurous motility characterized by gliding (lower inset, *Myxococcus fulvus* cells, 0.8 μm diameter). When nutrients are limiting, cells aggregate into swarming colonies (upper inset, *Myxococcus xanthus* colony on agar, 10 mm diameter) exhibiting social motility mediated by type IV pili and twitching. Cells eventually aggregate to form fruiting bodies, within which some vegetative cells develop into myxospores.

excretes slime, and as it moves across a solid surface, it leaves behind a slime trail (Figure 15.42). The vegetative cells form a swarm that exhibits self-organizing behavior, and this allows them to behave as a single coordinated entity in response to environmental cues.

Upon nutrient exhaustion, vegetative cells of myxobacteria begin to migrate toward each other, aggregating together in mounds or heaps (Figure 15.43). Aggregation is likely mediated by chemotactic or quorum-sensing responses (◀ Sections 7.6 and 7.7). As the cell masses become higher, they begin to differentiate into fruiting bodies (Figure 15.44) containing myxospores. Myxospores are specialized cells that are resistant to drying, ultraviolet radiation, and heat, but the degree of heat resistance is much less than that of the bacterial endospore (◀ Section 2.8). Fruiting bodies can be simple,

consisting of masses of myxospores embedded in slime, or complex, consisting of a stalk and heads (Figure 15.44). The fruiting body stalk is composed of slime within which a few cells are trapped. The majority of the cells migrate to the fruiting body head, where they undergo differentiation into myxospores (Figure 15.42).

15.17 Spirochetes

KEY GENERA: *Spirochaeta*, *Treponema*, *Cristispira*, *Leptospira*, *Borrelia*

Spirochetes are morphologically unique bacteria found only within the bacterial phylum *Spirochaetes*.

Spirochetes are gram-negative, motile, tightly coiled *Bacteria*, typically slender and flexuous in shape (Figure 15.45). Spirochetes are widespread in aquatic sediments and in animals. Some cause diseases, including syphilis, an important human sexually transmitted disease. Spirochetes are classified into eight genera (Table 15.2) primarily on the basis of habitat, pathogenicity, phylogeny, and morphological and physiological characteristics.

Spirochetes have an unusual mode of motility conveyed by their unusual morphology. Spirochetes contain *endoflagella*, which resemble normal flagella but are found in the cell periplasm (Figure 15.46). The endoflagella are anchored at the cell poles and extend back along the length of the cell. Both the endoflagella and the protoplasmic cylinder are surrounded by a flexible membrane called the *outer sheath* (Figure 15.46b). Endoflagella rotate, as do typical bacterial

Figure 15.43 Scanning electron micrographs of fruiting body formation in *Chondromyces crocatus*. (a) Early stage, showing aggregation and mound formation. (b) Initial stage of stalk formation. Slime formation in the head has not yet begun and so the cells that compose the head are still visible. (c) Three stages in head formation. Note that the diameter of the stalk also increases. (d) Mature fruiting bodies. The entire fruiting structure is about 600 μm in height (compare with Figure 15.41c).

Figure 15.44 The myxobacterium *Stigmatella aurantiaca*. Scanning electron micrograph of a fruiting body growing on a piece of wood. Note the individual cells visible in each fruiting body. Inset: Phase-contrast photomicrograph of a single fruiting body about 150 μm high. The color is due to the production of glucosylated carotenoid pigments.

flagella. However, when both endoflagella rotate in the same direction, the protoplasmic cylinder rotates in the opposite direction, placing torsion on the cell (Figure 15.46b). This torsion causes the spirochete cell to flex, resulting in a corkscrew-like motion that allows cells to burrow through viscous materials or tissues.

Spirochetes are often confused with spirilla. **Spirilla** are helically curved rod-shaped cells, usually motile by means of polar flagella (Figure 15.47). The word *spirillum* refers to a general cell shape that is widespread among *Bacteria* and *Archaea*. The number of helical turns in a single spirillum may vary from less than one complete turn (in which case the organism looks like a vibrio) to many turns. In addition, spirilla that divide terminally, such as the cyanobacterium *Spirulina* (Figure 15.5), can form long helical filaments that superficially resemble spirochetes. Spirilla, however, lack the outer sheath, endoflagella, and corkscrew-like motility of spirochetes. In addition, spirilla are typically fairly rigid cells while spirochetes are highly flexible and quite thin ($< 0.5 \mu\text{m}$).

Figure 15.46 Motility in spirochetes. (a) Electron micrograph of a negatively stained cell of *Spirochaeta zuelzeri*, showing the position of the endoflagellum; the cell is about 0.3 μm in diameter. (b) Diagram of a spirochete cell, showing the arrangement of the protoplasmic cylinder, endoflagella, and external sheath, and how rotation of the endoflagellum generates rotation of both the protoplasmic cylinder and the external sheath.

Spirochaeta and *Cristispira*

The genus *Spirochaeta* includes free-living, anaerobic, and facultatively aerobic spirochetes. These organisms, of which several species are known, are common in aquatic environments such as freshwater and sediments, and also in the oceans. *Spirochaeta plicatilis* (Figure 15.45b) is a large spirochete found in sulfidic freshwater and marine habitats. The 20 or so endoflagella inserted at each pole of *S. plicatilis* are arranged in a bundle that winds around the coiled protoplasmic cylinder. Another species, *Spirochaeta stenostrepta* (Figure 15.45a), is an obligate anaerobe commonly found in H_2S -rich black muds. It ferments sugars to ethanol, acetate, lactate, CO_2 , and H_2 .

Cristispira (Figure 15.48) is a unique spirochete found in nature only in the crystalline style of certain molluscs, such as clams and oysters. The crystalline style is a flexible, semisolid rod seated in a sac and rotated against a hard surface of the digestive tract, thereby mixing and grinding the small particles of food taken in by the animal. *Cristispira* lives in both freshwater and marine molluscs, but not all species of molluscs possess this organism. Unfortunately, *Cristispira* has not been cultured, and so the physiological rationale for its restriction to this unique habitat is unknown.

Figure 15.45 Morphology of spirochetes. Two spirochetes at the same magnification, showing the wide size range in the group. (a) *Spirochaeta stenostrepta*, by phase-contrast microscopy. A single cell is 0.25 μm in diameter. (b) *Spirochaeta plicatilis*. A single cell is 0.75 μm in diameter and can be up to 250 μm (0.25 mm) in length.

TABLE 15.2 Genera of spirochetes and their characteristics

Genus	Dimensions (μm)	General characteristics	Number of endoflagella	Habitat	Diseases
<i>Cristispira</i>	30–150 $\times$ 0.5–3.0	3–10 complete coils; bundle of endoflagella visible by phase-contrast microscopy	~100	Digestive tract of molluscs; has not been cultured	None known
<i>Spirochaeta</i>	5–250 $\times$ 0.2–0.75	Anaerobic or facultatively aerobic; tightly or loosely coiled	2–40	Aquatic, free-living, freshwater and marine	None known
<i>Treponema</i>	5–15 $\times$ 0.1–0.4	Microaerophilic or anaerobic; helical or flattened coil amplitude up to 0.5 μm	2–32	Commensal or parasitic in humans, other animals	Syphilis, yaws, swine dysentery, pinta
<i>Borrelia</i>	8–30 $\times$ 0.2–0.5	Microaerophilic; 5–7 coils of approximately 1 μm amplitude	7–20	Humans and other mammals, arthropods	Relapsing fever, Lyme disease, ovine and bovine borreliosis
<i>Leptospira</i>	6–20 $\times$ 0.1	Aerobic, tightly coiled, with bent or hooked ends; requires long-chain fatty acids	2	Free-living or parasitic in humans, other mammals	Leptospirosis
<i>Leptonema</i>	6–20 $\times$ 0.1	Aerobic; does not require long-chain fatty acids	2	Free-living	None known
<i>Brachyspira</i>	7–10 $\times$ 0.35–0.45	Anaerobe	8–28	Intestine of warm-blooded animals	Causes diarrhea in chickens and swine
<i>Brevinema</i>	4–5 $\times$ 0.2–0.3	Microaerophile; forms deep branch in spirochete lineage as assessed by 16S rRNA sequence analysis	2	Blood and tissue of mice and shrews	Infectious for laboratory mice

Treponema and Borrelia

Anaerobic or microaerophilic host-associated spirochetes that are commensals or pathogens of humans and animals reside in the genus *Treponema*. *T. pallidum*, the causal agent of syphilis (► Section 31.13), is the best-known species of *Treponema*. It differs in morphology from other spirochetes in that the *Treponema* cell is not helical but flat and wavy. The *T. pallidum* cell is remarkably thin, measuring only 0.2 μm in diameter. Because of this, dark-field microscopy has long been used to examine exudates from suspected syphilitic lesions (► Figure 31.13).

Other species of *Treponema* are also often found as commensals in humans and other animals. For example, *Treponema denticola* is common in the human oral cavity and is associated with gum disease. It ferments amino acids such as cysteine and serine, forming acetate as the major fermentation acid, as well as CO_2 , NH_3 , and H_2S . Spirochetes are also common in the rumen, the digestive forestomach of ruminant animals (► Section 23.15). For instance, *Treponema saccharophilum* (Figure 15.49a) is a large, pectinolytic spirochete found in the bovine rumen where it ferments pectin, starch, inulin, and other plant polysaccharides. *Treponema primitia* can be found in the hindgut of certain termites. In the termite gut, fermentation of cellulose causes production of H_2 and CO_2 . *T. primitia* is an acetogen (◄ Section 14.14) that grows on H_2 plus CO_2 , forming acetate, which is an important component of the insect's nutrition. *Treponema azotonutricium* is also found in the termite hindgut and is capable of nitrogen fixation (◄ Section 3.12).

The majority of species of *Borrelia* are animal or human pathogens. *Borrelia burgdorferi* (Figure 15.49b) is the causative agent of the tick-borne *Lyme disease*, which infects humans and animals (► Section 32.4). *B. burgdorferi* is also of interest because it is one of the few bacteria that has a linear (as opposed to a circular) chromosome (◄ Sections 6.2 and 10.3). Other species of *Borrelia* are primarily of veterinary importance, causing diseases in cattle, sheep, horses, and birds. In most cases, the bacterium is transmitted to the animal host from the bite of a tick.

Figure 15.48 *Cristispira*. Electron micrograph of a thin section of a cell of *Cristispira*. This large spirochete is about 2 μm in diameter. Notice the numerous endoflagella.

Leptospira and Leptonema

The genera *Leptospira* and *Leptonema* contain strictly aerobic spirochetes that oxidize long-chain fatty acids (for example, the C_{18} fatty acid oleic acid) as electron donors and carbon sources. With few exceptions, these are the only substrates utilized for growth. Leptospiras are thin, finely coiled, and usually bent at each end into a semicircular hook. At present, several species are recognized in this group, some free-living and many parasitic. Two major species of *Leptospira* are *L. interrogans* (parasitic) and *L. biflexa* (free-living). Strains of *L. interrogans* are parasitic for humans and animals. Rodents are the natural hosts of most leptospiras, although dogs and pigs are also important carriers of certain strains.

In humans the most common leptospiral syndrome is *leptospirosis*, a disorder in which the organism localizes in the kidneys and can

cause renal failure or even death. Leptospiras ordinarily enter the body through the mucous membranes or through breaks in the skin during contact with an infected animal. After a transient multiplication in various parts of the body, the organism localizes in the kidneys and liver, causing nephritis and jaundice. Domestic animals such as dogs are vaccinated against leptospirosis with a killed virulent strain in the combined distemper–leptospira–hepatitis vaccine.

15.18 Budding and Prosthecae/Stalked Bacteria

KEY GENERA: *Hyphomicrobium*, *Caulobacter*

The growth of most bacteria is coupled to cell division by the well-known process of binary fission (◀ Section 4.6 and Figure 4.8). In this section, we consider organisms that grow and divide in different ways, including budding and the formation of appendages. Budding and appendaged species often have life cycles that are distinct among bacteria.

Budding Division

As we learned in Section 4.10, budding bacteria divide as a result of unequal cell growth. Cell division in stalked and budding bacteria forms a totally new daughter cell, with the mother cell retaining its original identity (◀ Figure 4.18). In contrast, binary fission produces two equivalent cells.

A fundamental difference between budding bacteria and bacteria that divide by binary fission is the formation of new cell wall material from a single point (polar growth) rather than throughout the whole cell (intercalary growth) as in binary fission (Chapter 8). Several genera not normally considered to be budding bacteria show polar growth without differentiation of cell size (◀ Figure 4.18). An important consequence of polar growth is that internal structures, such as membrane complexes, are not partitioned in the cell division process and must be formed de novo. However, this has an advantage in that more complex internal structures can be formed in budding cells than in cells that divide by binary fission, since the latter cells would have to partition these structures between the two daughter cells. Not coincidentally, many budding bacteria, particularly phototrophic and chemolithotrophic species, contain extensive internal membrane systems.

Budding Bacteria: *Hyphomicrobium*

Two well-studied budding bacteria are closely related *Alphaproteobacteria*: *Hyphomicrobium* (Figure 15.50), which is chemoorganotrophic, and *Rhodomicrobium*, which is phototrophic. These organisms release buds from the ends of long, thin hyphae. The hypha is a direct cellular extension and contains cell wall, cytoplasmic membrane, and ribosomes, and can contain DNA.

Figure 15.50 shows the life cycle of *Hyphomicrobium*. The mother cell, which is often attached by its base to a solid substrate, forms

Figure 15.50 Stages in the *Hyphomicrobium* cell cycle. The single chromosome of *Hyphomicrobium* is circular.

a thin outgrowth that lengthens to become a hypha. At the end of the hypha, a bud forms. This bud enlarges, forms a flagellum, breaks loose from the mother cell, and swims away. Later, the daughter cell loses its flagellum and after a period of maturation forms a hypha and buds. More buds can also form at the hyphal tip of the mother cell, leading to arrays of cells connected by hyphae. In some cases, a bud begins to form directly from the mother cell without the intervening formation of a hypha, whereas in other cases a single cell forms hyphae from each end (Figure 15.51). Nucleoid replication events occur before the bud emerges, and then once a bud has formed, a copy of the chromosome moves down the hypha and into the bud. A cross-septum then forms, separating the still-developing bud from the hypha and mother cell (Figure 15.51).

Physiologically, *Hyphomicrobium* is a methylotrophic bacterium (Section 14.16 and Section 15.15), and it is widespread in freshwater, marine, and terrestrial habitats. Preferred carbon sources are

(a)

(b)

Figure 15.51 Morphology of *Hyphomicrobium*. (a) Phase-contrast micrograph of cells of *Hyphomicrobium*. Cells are about $0.7\ \mu\text{m}$ wide. (b) Electron micrograph of a thin section of a single *Hyphomicrobium* cell. The hypha is about $0.2\ \mu\text{m}$ wide.

methanol (CH_3OH), methylamine (CH_3NH_2), formaldehyde (CH_2O), and formate (HCOO^-). A fairly specific enrichment procedure for *Hyphomicrobium* is to use CH_3OH as an electron donor with nitrate (NO_3^-) as an electron acceptor in a dilute medium incubated under anoxic conditions. The only rapidly growing denitrifying bacterium known that uses CH_3OH as an electron donor is *Hyphomicrobium*, and so this procedure can select this organism out of a wide variety of environments.

Prosthecae and Stalked Bacteria

A variety of bacteria are able to produce cytoplasmic extrusions including stalks (Figure 15.52), hyphae, and appendages (Table 15.3). Extrusions of these kinds, which are smaller in diameter than the mature cell and contain cytoplasm and a cell wall, are collectively called **prosthecae** (Figure 15.53). Prosthecae allow organisms to attach to particulate matter, plant material, or other microorganisms in aquatic habitats. In addition, prosthecae can be used to increase the ratio of surface area to cell volume. Recall that the high surface-to-volume ratio of prokaryotic cells in general confers an increased ability to take up nutrients and expel wastes (Section 1.3). The unusual morphology of appendaged bacteria (Figure 15.53) carries this theme to an extreme and may be an evolutionary adaptation to life in oligotrophic (nutrient-poor) waters where these organisms are most commonly found.

Prosthecae may also function to reduce cell sinking. Because these organisms are aquatic and their metabolism is typically aerobic, prosthecae may keep cells from sinking into anoxic zones in their aquatic environments where they would be unable to respire. Some prosthecae bacteria produce gas vesicles (Section 2.7), which would also help prevent sinking.

Figure 15.52 Stalked bacteria. (a) A *Caulobacter* rosette. A single cell is about 0.5 μm wide. The five cells are attached by their stalks, which are also prosthecae. Two of the cells have divided, and the daughter cells have formed flagella. (b) Negatively stained preparation of a *Caulobacter* cell in division. (c) A thin section of *Caulobacter* showing that cytoplasm is present in the stalk. Parts b and c are transmission electron micrographs.

Caulobacter

Two common stalked bacteria are *Caulobacter* (Figure 15.52) and *Gallionella* (Figure 15.36). The former is a chemoorganotroph that produces a cytoplasm-filled stalk, that is, a prostheca, while the latter is a chemolithotrophic iron-oxidizing bacterium whose stalk is composed of ferric hydroxide [Fe(OH)₃] (Section 15.14). *Caulobacter* cells are often seen on surfaces in aquatic environments with the stalks of several cells attached to form *rosettes* (Figure 15.52a).

Figure 15.53 Prosthecae bacteria. (a) Electron micrograph of a shadow-cast preparation of *Asticcacaulis biprosthecum*, illustrating the location and arrangement of the prosthecae, the holdfast, and a swarmer cell. The swarmer cell breaks away from the mother cell and begins a new cell cycle. Cells are about 0.6 μm wide. (b) Negatively stained electron micrograph of a cell of *Ancalomicrobium adetum*. The prosthecae are bounded by the cell wall, contain cytoplasm, and are about 0.2 μm in diameter. (c) Electron micrograph of the star-shaped prosthecae bacterium *Stella*. Cells are about 0.8 μm in diameter.

At the end of the stalk is a structure called a *holdfast* by which the stalk anchors the cell to a surface.

The *Caulobacter* cell division cycle (Figure 15.54; ◀ Section 8.8 and Figure 8.20) is unique because cells undergo unequal binary fission. A stalked cell of *Caulobacter* divides by elongation of the cell followed by binary fission, and a single flagellum forms at the pole opposite the stalk. The flagellated cell so formed, called a *swarmer*, separates from the nonflagellated mother cell and eventually attaches to a new surface, forming a new stalk at the flagellated pole; the flagellum is then lost. Stalk formation is a necessary precursor of cell division and is coordinated with DNA synthesis (Figure 15.54). The cell division cycle in *Caulobacter* is thus more complex than simple binary fission or budding division because the stalked and swarmer cells are structurally different and the growth cycle must include both forms.

TABLE 15.3 Characteristics of major genera of stalked, appendaged (prosthecae), and budding Bacteria		
Characteristics	Genus	Phylogenetic group
Stalked bacteria		
Stalk an extension of the cytoplasm and involved in cell division	<i>Caulobacter</i>	Alphaproteobacteria
Stalk is an excretory product not containing cytoplasm (therefore it is not a prostheca)	<i>Gallionella</i>	Betaproteobacteria
Appendaged (prosthecae) bacteria		
Single or double prosthecae	<i>Asticcacaulis</i>	Alphaproteobacteria
Multiple prosthecae	<i>Prosthecomicrobium</i>	Alphaproteobacteria
Budding bacteria		
Phototrophic, produce hyphae	<i>Rhodomicrobium</i>	Alphaproteobacteria
Phototrophic, budding without hyphae	<i>Rhodopseudomonas</i>	Alphaproteobacteria
Chemoorganotrophic, buds on tips of slender hyphae	<i>Hyphomicrobium</i>	Alphaproteobacteria

Check Your Understanding

- How does budding division differ from binary fission? How does binary fission differ from the division process in *Caulobacter*?
- What advantage might a prosthecate organism have in a very nutrient-poor environment?

15.19 Sheathed Bacteria

KEY GENERA: *Sphaerotilus*, *Leptothrix*

Bacteria in many phyla form sheaths made of polysaccharide or protein that encase one or many cells. Sheaths often function to bind cells together into long multicellular filaments (Sections 15.3 and 15.12). *Sphaerotilus* and *Leptothrix* are filamentous bacteria that grow within a sheath and have a unique life cycle. Under favorable conditions, the cells grow vegetatively, leading to the formation of long, cell-packed sheaths. Flagellated swarmer cells form within the sheath under unfavorable growth conditions, and the swarmer cells break out and are dispersed to new environments, leaving behind the empty sheath.

Sphaerotilus and *Leptothrix* are common in freshwater habitats that are rich in organic matter, such as wastewaters and polluted streams. Because they are typically found in flowing waters, they are also abundant in trickling filters and activated sludge digesters in sewage treatment plants (► Section 22.6). In habitats in which reduced iron (Fe^{2+}) or manganese (Mn^{2+}) is present, the sheaths may become coated with ferric hydroxide [$\text{Fe}(\text{OH})_3$] or manganese oxides from the oxidation of these metals.

Leptothrix

The ability of *Sphaerotilus* and *Leptothrix* to precipitate iron oxides on their sheaths is well established, and when sheaths become iron encrusted, as occurs in iron-rich waters, they can frequently be seen microscopically (Figure 15.55). Iron precipitates form when ferrous iron (Fe^{2+}), chelated to organic materials such as humic or tannic acids, is oxidized. These chemoorganotrophic bacteria use the organic materials as a carbon or energy source and, when no longer chelated, the ferrous iron becomes oxidized and precipitates on the

Figure 15.55 *Leptothrix* and iron precipitation. Transmission electron micrograph of a thin section of *Leptothrix* growing in a ferromanganese film in a swamp in Ithaca, New York. A single cell measures about $0.9\ \mu\text{m}$ in diameter. Note the protruberances of the cell envelope that contact the sheath (arrows).

sheath. Iron oxidation is fortuitous and though these organisms are closely related to dissimilative iron-oxidizers (Section 15.14), the organism does not gain energy from iron oxidation. In a similar way, *Leptothrix* can also oxidize manganese.

Sphaerotilus

The *Sphaerotilus* filament is composed of a chain of rod-shaped cells enclosed in a closely fitting sheath. This thin, transparent structure is difficult to see when it is filled with cells, but when it is partially empty, the sheath can more easily be resolved (Figure 15.56a). Individual cells are $1\text{--}2 \times 3\text{--}8\ \mu\text{m}$ in dimensions and stain gram-negatively. The cells within the sheath (Figure 15.56b) divide by binary fission, and the new cells synthesize new sheath material at the tips of the filaments. Eventually, motile swarmer cells are liberated from the sheaths (Figure 15.56c) and then migrate, attach to a solid surface, and begin to grow, with each swarmer being the forerunner of a new filament. The sheath, which is devoid of peptidoglycan, consists of protein and polysaccharide.

Sphaerotilus species are nutritionally versatile and use simple organic compounds as carbon and energy sources; one species can grow mixotrophically with thiosulfate as electron donor. Befitting its habitat in flowing waters, *Sphaerotilus* is an obligate aerobe. Large masses (blooms) of *Sphaerotilus* often occur in the fall of the year in streams and brooks when leaf litter causes a temporary increase in the organic content of the water. In addition, its filaments are the main component of a microbial complex that wastewater engineers call “sewage fungus,” a filamentous slime found on the rocks in streams receiving sewage pollution. In activated sludge of sewage treatment plants (► Section 22.6), *Sphaerotilus* is often responsible for a condition called *bulking*, where the tangled masses of *Sphaerotilus* filaments so increase the bulk of the sludge that it remains suspended and does not settle as it should. This has a negative effect on the oxidation of organic matter and the recycling of inorganic nutrients and leads to treatment plant discharges with high nitrogen and carbon loads.

Figure 15.56 *Sphaerotilus natans*. A single cell is about 2 μm wide. (a) Phase-contrast photomicrographs of material collected from a polluted stream. Active growth stage (above) and swarmer cells leaving the sheath. (b) Electron micrograph of a thin section through a filament, clearly showing the sheath. (c) Electron micrograph of a negatively stained swarmer cell. Notice the polar flagellar tuft.

Check Your Understanding

- Describe how a sheathed bacterium such as *Sphaerotilus* grows.
- List two metals that are oxidized by sheathed bacteria.

15.20 Magnetic Microbes

KEY GENERA: *Magnetospirillum*

In a magnetic field, magnetic bacteria demonstrate a dramatic directed movement called *magnetotaxis*. Within these cells are structures called *magnetosomes*, which consist of chains of magnetic particles made of magnetite (Fe_3O_4) or greigite (Fe_3S_4) (◀ Section 2.7 and Figure 2.24). Magnetosomes are localized within invaginations of the cell membrane that are organized in a linear conformation by a protein scaffold. Magnetic bacteria orient along the north–south

magnetic moment of a magnetic field, aligning parallel to the field lines in much the same manner as a compass needle. Magnetic bacteria are typically microaerophilic or anaerobic and are most often found near the oxic–anoxic interface in sediments or stratified lakes. The magnetosomes of aerobic species typically contain the mineral magnetite while those of anaerobes contain exclusively greigite.

Although the ecological role of bacterial magnets is unclear, the ability to orient in a magnetic field may be of selective advantage in maintaining these organisms in zones of low O_2 concentration. Generally, the concentration of O_2 decreases with depth through sediments or the water column of stratified lakes. Since Earth is spherical, its magnetic field lines have a strong vertical component in the Northern and Southern Hemispheres. Thus, bacteria that orient along these field lines can preferentially swim down and away from O_2 . The magnetosome functions like a compass needle to “point” the bacterium in the right direction; rotation of the flagellum, by contrast, is controlled by a chemotactic response to O_2 (◀ Section 2.11).

Magnetic bacteria display one of two magnetic polarities depending on the orientation of magnetosomes within the cell. Cells in the Northern Hemisphere have the north-seeking pole of their magnetosomes forward with respect to their flagella and thus move in a northward direction (which in the Northern Hemisphere is downward). Cells in the Southern Hemisphere have the opposite polarity and move southward.

Most of the magnetic bacteria that have been described are species of *Alphaproteobacteria*, but species have also been observed in the *Gammaproteobacteria*, the *Deltaproteobacteria*, and the *Nitrospira* group. One of the best-characterized species is *Magnetospirillum magnetotacticum* (Figure 15.57), which is a chemoorganotrophic microaerophile that can also grow anaerobically by reducing NO_3^- or

Figure 15.57 A magnetotactic spirillum. Electron micrograph of a single cell of *Magnetospirillum magnetotacticum*; a cell measures $0.3 \times 2 \mu\text{m}$. The cell contains particles of magnetosomes made of Fe_3O_4 arranged in a chain.

N₂O. In contrast, the species *Desulfovibrio magneticus* is a sulfate reducer and an obligate anaerobe. In addition, magnetosomes have been observed in a few species of sulfur oxidizers and purple non-sulfur bacteria. Multicellular magnetotactic bacteria are also known. These are *Deltaproteobacteria* that form multicellular aggregates of 10–20 cells organized as a hollow sphere. While multicellular magnetotactic bacteria are obligate anaerobes, the basis of their metabolism has not yet been determined.

We transition now from viewing *Bacteria* through the lens of their ecological diversity to consider some other important phyla in a

phylogenetic context in Chapter 16. We then conclude our coverage of prokaryotic microbes with Chapter 17 dedicated to the *Archaea*.

Check Your Understanding

- What benefit do magnetic bacteria accrue from having magnetosomes?
- Would you expect to find greigite or magnetite in the magnetosomes of *Desulfovibrio magneticus*?

CHAPTER REVIEW

I • Ecological Diversity Among Microorganisms

- 15.1** Microbial diversity can be defined in several different ways. Metabolic diversity is defined in terms of the cellular processes that support growth. Ecological diversity is defined in terms of microbial interactions between organisms and their environments. Phylogenetic diversity is defined by evolutionary relationships between organisms.

Q What is convergent evolution and how is it different from horizontal gene transfer?

II • Ecological Diversity of Phototrophic *Bacteria*

- 15.2** Anoxygenic phototrophs, which do not produce oxygen, were the first phototrophic organisms to evolve. The evolution of photosynthesis has been affected strongly by patterns of horizontal gene transfer.

Q Which phyla of *Bacteria* contain anoxygenic phototrophs? Which phylum contains purple sulfur bacteria? Which phylum contains green sulfur bacteria?

- 15.3** *Cyanobacteria* is the only bacterial phylum that contains oxygenic phototrophs. All species of cyanobacteria can fix CO₂ and many can fix N₂, making these organisms important primary producers in many ecosystems.

Q Which morphological groups can *Cyanobacteria* be divided into?

- 15.4** Purple sulfur bacteria are anoxygenic phototrophic *Gammaproteobacteria*. Purple sulfur bacteria use H₂S and S⁰ as electron donors and fix CO₂ by the Calvin cycle. These phototrophs have bacteriochlorophylls *a* or *b* and use a Q-type reaction center.

Q Compare and contrast the metabolism, morphology, and phylogeny of purple sulfur and purple nonsulfur bacteria.

- 15.5** Purple nonsulfur bacteria are anoxygenic phototrophic *Alpha*- and *Betaproteobacteria*. Purple nonsulfur bacteria are metabolically diverse, growing best as photoheterotrophs, and can also grow in darkness. These phototrophs have bacteriochlorophylls *a* or *b* and use type II photosystems with Q-type reaction centers. Aerobic anoxygenic phototrophs have type II photosystems but only possess bacteriochlorophyll *a*.

Q In what metabolic ways are aerobic anoxygenic phototrophs and purple nonsulfur bacteria similar? How do they differ?

- 15.6** Green sulfur bacteria are anoxygenic phototrophs of the phylum *Chlorobi*. Green sulfur bacteria use H₂S or S⁰ as electron donors and fix CO₂ by the reverse citric acid cycle. These phototrophs contain bacteriochlorophylls *c*, *d*, or *e* localized in chlorosomes and bacteriochlorophyll *a* localized in their FeS-type photosynthetic reaction centers.

Q Compare and contrast the metabolism, morphology, and phylogeny of green sulfur and purple sulfur bacteria.

- 15.7** Green nonsulfur bacteria, also known as filamentous anoxygenic phototrophs, are anoxygenic phototrophs of the phylum *Chloroflexi* and grow best as photoheterotrophs. These phototrophs contain bacteriochlorophyll *c* in chlorosomes and bacteriochlorophyll *a* in their Q-type photosynthetic reaction centers.

Q What traits do green nonsulfur bacteria share with green sulfur bacteria and purple sulfur bacteria?

- 15.8** Heliobacteria are anoxygenic phototrophic *Firmicutes* that grow as photoheterotrophs or in darkness as chemotrophs. Heliobacteria produce bacteriochlorophyll *g* and have FeS-type reaction centers. *Chloracidobacterium thermophilum* is an anoxygenic phototrophic acidobacterium that grows photoheterotrophically, possesses bacteriochlorophyll *a* and *c* as well as chlorosomes, and has an FeS-type reaction center.

Q In what ways is *Chloracidobacterium thermophilum* similar to green sulfur bacteria, and in what ways is it different?

III • Diversity of *Bacteria* Defined by Metabolic Traits

- 15.9** Diazotrophs are bacteria that assimilate N₂ through activity of the enzyme nitrogenase. Diazotrophs are metabolically and phylogenetically diverse and employ various adaptations to protect nitrogenase from oxygen inactivation.

Q What are some ways that diazotrophs protect nitrogenase from O₂?

- 15.10** Nitrifying bacteria are aerobic chemolithotrophs that oxidize NH_3 to NO_2^- (genus prefix *Nitroso-*) or NO_2^- to NO_3^- (genus prefix *Nitro-*). Ammonia oxidizers are *Proteobacteria* or *Thaumarchaeota*, while nitrite oxidizers are *Proteobacteria* or *Nitrospirae*. Denitrifiers are metabolically and phylogenetically diverse facultative aerobes and chemoorganotrophs that reduce NO_3^- to the gaseous products NO , N_2O , and N_2 .

Q Compare and contrast the nitrogen metabolism of nitrifiers with that of denitrifiers.

- 15.11** Dissimilative sulfate-reducers are obligate anaerobes that grow by reducing SO_4^{2-} with H_2 or simple organic compounds as electron donors. Most sulfate reducers are *Delta-proteobacteria*. Dissimilative sulfur-reducers are metabolically and phylogenetically diverse organisms that grow by reducing S^0 and other oxidized sulfur compounds (other than SO_4^{2-}) as electron acceptors.

Q With respect to sulfate-reducing bacteria and acetate as substrate, which genera contain “incomplete oxidizers” and which genera contain “complete oxidizers”? What are the physiological traits that can differentiate sulfur-reducing bacteria from sulfate-reducing bacteria?

- 15.12** Sulfur chemolithotrophs, most of which are species of *Proteobacteria*, oxidize H_2S and other reduced sulfur compounds as electron donors with O_2 or NO_3^- as electron acceptors and use either CO_2 or organic compounds as carbon sources. Sulfur chemolithotrophs use a variety of ecological strategies to conserve energy from H_2S and O_2 , substances that otherwise react together spontaneously.

Q What are some ecological strategies that aerobic sulfide-oxidizers use to compete with the chemical oxidation of H_2S by atmospheric O_2 ?

- 15.13** Dissimilative iron-reducers reduce insoluble electron acceptors in anaerobic respirations. Most species can grow anaerobically by reducing ferric iron using H_2 or simple organic compounds as electron donor. The best-characterized genera include *Geobacter*, which contains exclusively obligate anaerobes, and *Shewanella*, which contains facultative aerobes.

Q In what ways are the dissimilative iron-reducing bacteria *Shewanella* and *Geobacter* similar, and in what ways are they different?

- 15.14** Dissimilative iron-oxidizers conserve energy from the aerobic oxidation of ferrous iron. These microbes use several ecological strategies to cope with the chemical instability of ferrous iron in oxic habitats at neutral pH. Iron oxidizers are found in four physiological groups: aerobic acidophiles, aerobic neutrophiles, anaerobic chemotrophs, and anaerobic phototrophs.

Q Which group of dissimilative iron-oxidizers is the least diverse, and in what way is this related to oxygen and pH?

- 15.15** Methylotrophs grow on organic compounds that lack carbon-carbon bonds. Some methylotrophs are also methanotrophs, organisms able to catabolize methane. Most methanotrophs are *Proteobacteria* that contain extensive internal membranes and incorporate carbon by either the serine or ribulose monophosphate pathways.

Q What are the differences between type I and type II methanotrophs?

IV • Morphologically and Ecologically Distinctive Bacteria

- 15.16** Bacterial predators such as *Bdellovibrio* and *Myxococcus* consume other microorganisms. Myxobacteria have a complex developmental cycle that involves the formation of fruiting bodies that contain myxospores.

Q Compare and contrast the life cycle of *Myxococcus* with that of *Bdellovibrio*.

- 15.17** The phylum *Spirochaetes* contains helically shaped bacteria that show a novel form of motility that allows them to “corkscrew” through viscous materials. These organisms are common in anoxic habitats and are the cause of many well-known human diseases, such as syphilis.

Q Contrast the motility of spirochetes with that of spirilla.

- 15.18** Prosthecate bacteria, such as *Hyphomicrobium*, *Caulobacter*, and *Gallionella*, are appendaged cells that form stalks or prosthecae used for attachment or nutrient absorption and are primarily aquatic. Some prosthecate bacteria, such as *Hyphomicrobium*, have a complex life cycle in which new cells form by budding from hyphae.

Q Contrast the life cycle of *Hyphomicrobium* with that of *Caulobacter*.

- 15.19** Sheathed bacteria are filamentous *Proteobacteria* in which individual cells form chains within an outer layer called the sheath. *Sphaerotilus* and *Leptothrix* are major genera of sheathed bacteria and can oxidize metals, such as Fe^{2+} and Mn^{2+} .

Q In what environment might you expect to find *Leptothrix*?

- 15.20** Magnetosomes are specialized magnetic structures present in magnetotactic bacteria. Magnetosomes orient cells along the magnetic field lines of Earth, and this allows cells to use their normal chemotactic response to move vertically in a directed fashion in sediments or stratified aquatic systems.

Q In what way does a magnetosome contribute to the fitness of microaerophilic bacteria in sediments?

APPLICATION QUESTIONS

- Describe a key physiological feature of the following *Bacteria* that would differentiate each from the others: *Rhodobacter*, *Methylococcus*, *Azotobacter*, *Desulfovibrio*, and *Spirillum*.
- Describe the metabolism for each of the following *Bacteria* and state whether the organism is an aerobe or an anaerobe: *Thiobacillus*, *Nitrosomonas*, *Methylomonas*, *Heliobacterium*, *Rhodospirillum*, *Myxococcus*, and *Gallionella*.

3. Using an example from each of the morphologically diverse groups of *Bacteria* (Sections 15.16–15.20), describe how you could distinguish them from each other using only microscopy. How do the habitats of your example organisms differ

from each other? Could you find any of these organisms in or on the human body? Despite their ability to oxidize inorganic electron donors, why are *Sphaerotilus* and *Leptothrix* not considered chemolithotrophs?

CHAPTER GLOSSARY

Aerobic anoxygenic phototroph an organism that is an aerobic heterotroph that uses anoxygenic photosynthesis as a supplemental source of energy

Carboxysome a polyhedral cellular inclusion of crystalline ribulose biphosphate carboxylase (RuBisCO), the key enzyme of the Calvin cycle

Chemolithotroph an organism able to oxidize inorganic compounds (such as H_2 , Fe^{2+} , S^0 , or NH_4^+) as energy sources (electron donors)

Chlorosome a cigar-shaped structure present in the periphery of cells of green sulfur and green nonsulfur bacteria and containing the antenna bacteriochlorophylls (*c*, *d*, or *e*)

Consortium a two- or more-membered association of bacteria, usually living in an intimate symbiotic fashion

Convergent evolution a circumstance where a trait or set of traits that are similar in form and/or function between two organisms are not inherited from a shared ancestor (that is, the traits are similar but not homologous)

Cyanobacteria prokaryotic oxygenic phototrophs containing chlorophyll *a* and in most cases phycobilins

Denitrifier an organism that carries out anaerobic respiration with NO_3^- or NO_2^- , reducing it to the gaseous products NO , N_2O , and N_2

Diazotroph an organism that can assimilate N_2 into biomass by activity of the enzyme nitrogenase

Dissimilative sulfate-reducer an anaerobic microorganism that conserves energy through the reduction of SO_4^{2-}

Dissimilative sulfur-oxidizer a microorganism that gains energy for growth

through oxidation of reduced sulfur compounds

Dissimilative sulfur-reducer an anaerobic or facultatively aerobic microorganism that conserves energy through the reduction of S^0 but cannot reduce SO_4^{2-}

Ecological diversity a concept for understanding microbial diversity that defines diversity in terms of differences in the interactions between organisms and their environments.

Green nonsulfur bacteria anoxygenic phototrophs containing chlorosomes, Q-type photosynthetic reaction centers, bacteriochlorophylls *a* and *c* as light-harvesting chlorophylls, and typically growing best as photoheterotrophs

Green sulfur bacteria anoxygenic phototrophs containing chlorosomes, FeS-type photosynthetic reaction centers, bacteriochlorophylls *c*, *d*, or *e* as antenna bacteriochlorophylls, and typically growing with H_2S as an electron donor

Helibacteria anoxygenic phototrophs containing bacteriochlorophyll *g* and FeS-type reaction centers

Horizontal gene transfer the unidirectional transfer of genes between cells through a process uncoupled from reproduction

Metabolic diversity a concept for understanding microbial diversity that defines diversity in terms of differences in the cellular processes that support microbial growth

Methanotroph an organism capable of oxidizing methane (CH_4) as an electron donor in energy metabolism

Methylotroph an organism capable of oxidizing organic compounds that do not

contain carbon–carbon bonds; if able to oxidize CH_4 , also a methanotroph

Mixotroph an organism that conserves energy from the oxidation of inorganic compounds but requires organic compounds as a carbon source

Nitrifier a chemolithotroph capable of carrying out the oxidation of NH_3 or NO_2^-

Phycobilins the pigments phycocyanin, allophycocyanin, and phycoerythrin that function as photosynthetic accessory pigments in cyanobacteria and are coupled to proteins to form phycobiliproteins

Phylogenetic diversity a concept for understanding microbial diversity that defines diversity in terms of differences in the evolutionary relationships between organisms

Prochlorophyte a bacterial oxygenic phototroph that contains chlorophylls *a* and *b* but lacks phycobilins

Prosthecae extrusions of cytoplasm, often forming distinct appendages, bounded by the cell wall

Purple nonsulfur bacteria a group of phototrophic bacteria that contain bacteriochlorophyll *a* or *b* and Q-type reaction centers, and that grow best as photoheterotrophs

Purple sulfur bacteria a group of phototrophic bacteria that contain bacteriochlorophylls *a* or *b*, have Q-type reaction centers, and can oxidize H_2S as photosynthetic electron donor

Spirilla (singular, spirillum) spiral-shaped cells

Spirochete a slender, tightly coiled, gram-negative bacterium of the phylum *Spirochaetes* characterized by possession of endoflagella used for motility

Phylogenetic Diversity of *Bacteria*

16

MICROBIOLOGYNOW

Bacterial Diversity and Human Health

Animals, particularly those that eat plants, have gut microbes that convert food into nutrients for the host. These animals lack enzymes for digesting the lignin and cellulose of plant cell walls and have evolved specialized organs that house microbes to perform these tasks. In humans, this organ is the colon, also known as the large intestine.

The average human colon contains hundreds of microbial species, and up to a hundred trillion microbial cells, many of which belong to the order *Clostridiales* within the phylum *Firmicutes*. The *Clostridiales* are a highly diverse group of gram-positive anaerobes that employ a fermentative metabolism. *Clostridiales* are crucial to gut function, and changes in their abundance and diversity can have important consequences for human health.

Christensenella minuta (see scanning electron micrograph), a member of the *Clostridiales*, was first discovered in human feces. *C. minuta* is a strictly anaerobic, nonsporulating and nonmotile fermentative bacterium that ferments sugars to short-chain fatty acids, H₂, and CO₂. *C. minuta*

often co-occurs with methane-producing *Archaea* and may grow syntrophically with these H₂-consuming organisms. Microbiome research suggests that *C. minuta* and other species of the family *Christensenellaceae* are indicators of a healthy gut. These bacteria are depleted in obese individuals as well as those suffering from metabolic syndrome, inflammatory bowel disease, Crohn's disease, and ulcerative colitis. In addition, the introduction of live cells of *C. minuta* into mice reduces their body fat levels compared with control mice given heat-killed cells. Moreover, the relative abundance of *Christensenellaceae* in the gut is genetically determined in humans, with up to 40% of variation in their relative abundance attributable to host genetics.

These results show that our genes influence our microbial relationships and that our gut microbes can influence our health. A full understanding of our gut health therefore depends upon our understanding of gut bacterial diversity.

- VI *Other Bacteria* 586

In the previous chapters we examined the *metabolic and ecological* diversity of microorganisms. In this and the next two chapters, we shift our focus to the *phylogenetic* diversity of microorganisms. We considered the difference between metabolic, ecological, and phylogenetic diversity in Section 15.1. In this chapter, we examine the major lineages of *Bacteria* (Figure 16.1a) and focus on the *Archaea* and microbial *Eukarya* in Chapters 17 and 18, respectively.

Including phyla of *Bacteria* known only from 16S ribosomal RNA (rRNA) gene sequences retrieved from the environment (► Sections 19.6 and 19.8), over 80 phyla can be distinguished. However, only about 30 of these contain species that have been characterized in laboratory culture (Figure 16.1b). Remarkably, more than 90% of cultivated genera and species of *Bacteria* originate in only four phyla: *Proteobacteria*, *Actinobacteria*, *Firmicutes*, and *Bacteroidetes* (Figure 16.1b).

With more than 12,000 species of bacteria described, we obviously cannot consider them all. Therefore, using phylogenetic trees to focus our discussion, we will explore some of the best-known

species from a broad diversity of phyla. In this chapter, we will consider species from 20 bacterial phyla, focusing on those with the largest numbers of characterized species. We begin our tour of the *Bacteria* with the phylum *Proteobacteria*, a hotbed of cultured species in this domain.

I • *Proteobacteria*

The *Proteobacteria* are divided into six classes, the *Alpha*-, *Beta*-, *Gamma*-, *Delta*-, *Epsilon*-, and *Zetaproteobacteria*. *Proteobacteria* is the largest and most metabolically diverse phylum of *Bacteria* and leads in numbers of cultivated and well-characterized species.

The *Proteobacteria* are by far the largest and most metabolically diverse phylum of *Bacteria* (Figure 16.2). More than a third of characterized species of *Bacteria* originate within this group

Figure 16.1 Some major phyla of *Bacteria* based on 16S ribosomal RNA gene sequence comparisons. (a) Depicted are the major phyla of *Bacteria* that have cultivated species. The area of each wedge is roughly proportional to the number of described cultivated species in each group. Analyses of 16S rRNA gene sequences from natural environments suggest there are more than 80 bacterial phyla. (b) Numbers of cultured and characterized species (green bars) and known 16S rRNA gene sequences (phylotypes, red bars) for each of the 29 major bacterial phyla that have at least one type species in pure culture. Also shown are related data for the different classes of *Proteobacteria*. Differences between the size of the red and green bars indicate the degree to which members of each group are common in natural environments but difficult to cultivate in isolation. Note that the abscissa is a log scale.

Figure 16.2 Phylogenetic tree and metabolic links of some key genera of *Proteobacteria*. Phylogeny of representative genera of *Proteobacteria* as revealed by analysis of 16S rRNA gene sequences. Note how identical metabolisms are often distributed in phylogenetically distinct genera, suggesting that horizontal gene flow has been extensive in the *Proteobacteria*. Some organisms listed may have multiple properties; for example, some sulfur chemolithotrophs are also iron or hydrogen chemolithotrophs, and several of the organisms listed can fix nitrogen. Phylogenetic analyses were performed and the phylogenetic tree constructed by Marie Asao, Ohio State University.

(Figure 16.1b), and *Proteobacteria* constitute the majority of known bacteria of medical, industrial, and agricultural significance.

As a group, the *Proteobacteria* are all gram-negative bacteria. They show an exceptionally wide diversity of energy-generating mechanisms, with chemolithotrophic, chemoorganotrophic, and phototrophic species (Figure 16.2). We have already encountered diverse representatives of this group in Chapters 14 and 15, where we considered the tremendous metabolic and ecological diversity of the *Proteobacteria*. Indeed, only a few types of metabolism do not occur within the *Proteobacteria*, including methanogenesis, which is only in *Archaea* (► Section 17.2); oxygenic phototrophy, which is only

in *Cyanobacteria* (◄ Section 15.3); anammox, which is only in *Planctomyces* (◄ Section 14.10); the complete oxidation of ammonia all the way to nitrate, a process called *comammox* (► Section 21.3), which is only found in *Nitrospirae* (Section 16.21); and anaerobic methanotrophy (◄ Section 14.16). The *Proteobacteria* are equally diverse in terms of their relationship to O₂, with anaerobic, microaerophilic, and facultatively aerobic species known. Morphologically, they also exhibit a wide range of cell shapes, including straight and curved rods, cocci, spirilla, and filamentous, budding, and appendaged forms (◄ Section 1.3 and Figure 1.8).

As we proceed through this chapter, we will need to recall the descending hierarchy of microbial systematics: domain (*Bacteria* or *Archaea*) → phylum → class → order → family → genus → species (◄ Section 13.12 and Table 13.1). We will use these terms frequently in this chapter. Based on 16S rRNA gene sequences, the phylum *Proteobacteria* can be divided into six classes: *Alpha*-, *Beta*-, *Gamma*-, *Delta*-, *Epsilon*-, and *Zetaproteobacteria*. Each class contains many genera with the exception of the *Zetaproteobacteria*, which is composed of a single characterized species, the marine iron-oxidizing bacterium *Mariprofundus ferrooxydans* (◄ Section 15.14).

Despite the phylogenetic breadth of the *Proteobacteria*, species in different classes often have similar metabolisms. For example, phototrophy and methylotrophy occur in three different classes of *Proteobacteria*, and nitrifying bacteria span four classes of *Proteobacteria* (◄ Figure 15.1). This suggests that horizontal gene flow (Chapter 9 and ◄ Section 13.9) has played a major role in shaping the metabolic diversity of the *Proteobacteria*. The sharing of metabolic traits in the different classes of *Proteobacteria* is also a good reminder that phenotype and phylogeny often provide different views of prokaryotic diversity (◄ Section 15.1).

16.1 Alphaproteobacteria

With about one thousand described species, the *Alphaproteobacteria* are the second largest class of *Proteobacteria* (Figure 16.1b). The *Alphaproteobacteria* contain extensive functional diversity (Figure 16.2, ◄ Figure 15.1), and many genera in this group have already been considered in Chapters 14 and 15. Most species are obligate aerobes or facultative aerobes and many are **oligotrophic**, preferring to grow in environments that have low nutrient concentrations. There are 10 well-characterized orders within the *Alphaproteobacteria*, but the vast majority of species fall within the *Rhizobiales*, *Rickettsiales*, *Rhodobacterales*, *Rhodospirillales*, *Caulobacterales*, and *Sphingomonadales* (Figure 16.3 and Table 16.1).

Rhizobiales

KEY GENERA: *Bartonella*, *Methylobacterium*, *Pelagibacter*, *Rhizobium*, *Agrobacterium*

The *Rhizobiales* (Figure 16.3) are the largest and most metabolically diverse order of *Alphaproteobacteria* and contain phototrophs (e.g., *Rhodopseudomonas*), chemolithotrophs (e.g., *Nitrobacter*), symbionts (e.g., rhizobia), free-living nitrogen-fixing bacteria (e.g., *Beijerinckia*), a few pathogens of plants and animals, and diverse chemoorganotrophs. The group gets its name from the *rhizobia*, a *polyphyletic* collection of genera that form root nodules and fix nitrogen in symbiotic association with leguminous plants (► Section 23.4).

Figure 16.3 Major orders of *Proteobacteria* in the class *Alphaproteobacteria*. The phylogenetic tree was constructed using 16S rRNA gene sequences from representative genera of *Alphaproteobacteria*. Order names are shown in bold.

Among the *Rhizobiales* are nine genera that contain rhizobia: *Bradyrhizobium*, *Ochrobactrum*, *Azorhizobium*, *Devosia*, *Methylobacterium*, *Mesorhizobium*, *Phyllobacterium*, *Sinorhizobium*, and *Rhizobium*. These are typically chemoorganotrophs and obligate aerobes, and the genes that convey the ability to form root nodules have been distributed among these genera by horizontal gene transfer. Indeed, nodulation genes are found on large plasmids that can be transferred between cells (► Section 23.4). Each rhizobial genus has a distinct range of plant hosts that can be colonized (► Table 23.1). Rhizobia can be isolated by crushing nodules and spreading their contents on nutrient-rich solid media; colonies typically produce copious amounts of exopolysaccharide slime (Figure 16.4).

The organism *Agrobacterium tumefaciens* (also called *Rhizobium radiobacter*) is closely related to root nodule *Rhizobium* species but is a plant pathogen that causes crown gall disease (► Section 23.6). *A. tumefaciens* is unable to form root nodules, and the genes that encode gall formation are also found on a plasmid. These pathogenicity genes, however, are unrelated to the plasmid-borne genes that mediate nodule formation in symbiotic rhizobia.

The genus *Methylobacterium* is one of the largest in the *Rhizobiales*. These species are often called “pink-pigmented facultative methylotrophs” because of the pink color of their colonies (◄ Section 15.15) and their good growth on methanol. Species are commonly found on the surface of plants and in soils and freshwater systems. These organisms are also commonly encountered in toilets and baths

TABLE 16.1 Notable genera of <i>Alphaproteobacteria</i>		
Order	Genus	Notable characteristics
Caulobacterales	<i>Caulobacter</i>	Asymmetric cell division and formation of prosthecae
Rickettsiales	<i>Rickettsia</i>	Obligate intracellular parasites of humans, transmitted by arthropods
	<i>Wolbachia</i>	Obligate intracellular parasites of arthropods, affect their reproduction, lack peptidoglycan
Rhizobiales	<i>Bartonella</i>	Obligate intracellular parasites, transmitted by arthropods
	<i>Bradyrhizobium</i>	Form root nodules with soybean and other legumes
	<i>Brucella</i>	Facultative intracellular parasites of animals, zoonotic pathogen
	<i>Hyphomicrobium</i>	Stalked cells, metabolically versatile
	<i>Mesorhizobium</i>	Form root nodules with bird's-foot trefoil and other legumes
	<i>Methylobacterium</i>	Methylotroph found on plants and in soil
	<i>Nitrobacter</i>	Nitrifying bacterium that oxidizes NO ₂ ⁻ to NO ₃ ⁻
	<i>Pelagibacter</i>	Oligotrophic chemoorganotroph; high abundance in ocean surface
	<i>Rhodopseudomonas</i>	Metabolically versatile purple nonsulfur bacterium
Rhodobacterales	<i>Paracoccus</i>	Species used as a model for studying denitrification
	<i>Rhodobacter</i>	Metabolically versatile purple nonsulfur bacteria
	<i>Roseobacter</i>	Aerobic anoxygenic phototroph
Rhodospirillales	<i>Acetobacter</i>	Used industrially for producing acetic acid
	<i>Azospirillum</i>	Obligately aerobic diazotroph
	<i>Gluconobacter</i>	Used industrially for producing acetic acid
	<i>Magnetospirillum</i>	Magnetotactic bacterium
Sphingomonadales	<i>Sphingomonas</i>	Aerobic degradation of aromatic organics, biodegradation
	<i>Zymomonas</i>	Ferments sugars into ethanol, potential for biofuel production

where their growth on shower curtains, caulk, and in toilet bowls results in the formation of pink-pigmented biofilms. Species of *Methylobacterium* are readily isolated by pressing the surface of a plant leaf onto an agar Petri plate containing methanol as the sole source of carbon.

Ocdle Berge

Figure 16.4 Colonies of *Rhizobium mongolense*. Colonies of rhizobia often produce copious exopolysaccharide slime. These colonies of *Rhizobium mongolense* were grown on a medium low in nitrogen with sucrose as carbon source.

Bartonella is another notable genus of *Rhizobiales*. These organisms, once classified with the *Rickettsiales*, are intracellular pathogens of humans. Species of *Bartonella* can cause a variety of diseases in humans and other vertebrate animals. *Bartonella quintana* is the causative agent of *trench fever*, a disease that got its name because it decimated soldiers in the brutal trench warfare practiced in World War I. Other species of *Bartonella* can cause bartonellosis, cat scratch disease, and a variety of inflammatory diseases. These diseases are mediated by arthropod vectors including fleas, lice, and sand flies (Chapter 32). Species of *Bartonella* are fastidious and difficult to cultivate, and isolation is most commonly achieved using blood agar. When growing in tissue culture, cells of *Bartonella* grow on the outside surface of the eukaryotic host cells rather than within the cytoplasm or the nucleus.

Finally, the genus *Pelagibacter* also belongs to the *Rhizobiales*. *Pelagibacter ubique* is an oligotroph and an obligately aerobic chemotroph that inhabits the photic zone of Earth's oceans. This organism can make up 25% of the bacterial cells found at the ocean's surface, and its numbers can reach 50% of cells in temperate waters in the summer; as a consequence, *Pelagibacter ubique* is likely the most abundant bacterial species on Earth (► Section 20.12).

Rickettsiales

KEY GENERA: *Rickettsia*, *Wolbachia*

Rickettsiales (Figure 16.3) are all obligate intracellular parasites or mutualists of animals. Species in this order have not yet been cultivated in the absence of host cells (Figure 16.5) and must be grown in chicken eggs or in host cell tissue culture. Typically, *Rickettsiales* are closely associated with arthropods. Those genera that cause disease, such as *Rickettsia* and *Ehrlichia*, are transmitted by arthropod bites; other genera such as *Wolbachia* are obligate parasites or mutualists of insects and other arthropods.

Species of the genus *Rickettsia* are the causative agents of several human diseases, including typhus (*Rickettsia prowazekii*) and spotted fever rickettsiosis, commonly called Rocky Mountain spotted fever (*Rickettsia rickettsii*) (► Section 32.3). These organisms are closely associated with arthropod vectors and can be transmitted by ticks, fleas, lice, and mites. Most rickettsias are metabolically specialized, able to oxidize only the amino acids glutamate or glutamine and unable to oxidize glucose or organic acids. Rickettsias are unable to synthesize certain metabolites and must instead obtain them from host cells. Rickettsias do not survive long outside their hosts, and

Willy Burgdorfer

(b)

Figure 16.5 Rickettsias growing within host cells. (a) *Rickettsia rickettsii* in tissue culture. Cells are about 0.3 μm in diameter. (b) Electron micrograph of cells of *Rickettsia popilliae* within a blood cell of its host, the beetle *Melolontha melolontha*. The bacteria grow inside a vacuole within the host cell.

this may explain why they must be transmitted from animal to animal by arthropod vectors.

Electron micrographs of thin sections of rickettsial cells show a typical prokaryotic morphology including a cell wall (Figure 16.5b). The penetration of a host cell by a rickettsial cell is an active process, requiring both host and parasite to be viable and metabolically active. Once inside the host cell, the bacteria multiply primarily in the cytoplasm and continue replicating until the host cell is loaded with parasites (Figure 16.5; ► Figures 32.6 and 32.7). The host cell then bursts and liberates the bacterial cells.

The genus *Wolbachia* contains intracellular parasites found within many arthropods and some nematodes (Figure 16.6). Species of *Wolbachia* infect an enormous diversity of insect species, and 10–70% of individual insects in a susceptible species carry *Wolbachia*. *Wolbachia* species can have any of several effects on their insect hosts. These include inducing parthenogenesis (development of unfertilized eggs), the killing of males, and feminization (the conversion of male insects into females). *Wolbachia*, because of their ability to alter host reproduction, have a major impact on the evolution of their insect hosts (► Section 23.7).

Wolbachia pipiensis is the best-studied species in the genus. Cells of *W. pipiensis* colonize the insect egg (Figure 16.6), where they multiply in vacuoles of host cells surrounded by a membrane of host origin. *Wolbachia* lack a cell wall and the ability to make peptidoglycan. Peptidoglycan can trigger host immune responses (Chapter 26), and the loss of genes for peptidoglycan synthesis helps this obligate

Figure 16.6 *Wolbachia*. Photomicrograph of a DAPI-stained egg of the parasitoid wasp *Trichogramma kaykai* infected with *Wolbachia pipientis*, which induces parthenogenesis. The *W. pipientis* cells are primarily located in the narrow end of the egg (arrows).

intracellular organism escape host immune detection. Cells of *W. pipientis* are passed from an infected female to her offspring through infected eggs. *Wolbachia*-induced parthenogenesis occurs in a number of species of wasps. In the normal reproductive cycle of these insects, eggs that are unfertilized (and haploid) develop into males, while eggs that are fertilized (and diploid) develop into females. However, *Wolbachia* infection triggers a doubling of chromosome number in haploid eggs, and so an infected mother can only lay female eggs that contain her own DNA. Predictably, if female insects are fed antibiotics that kill *Wolbachia*, parthenogenesis ceases.

Other Groups of Alphaproteobacteria

KEY GENERA: *Rhodobacter*, *Acetobacter*, *Caulobacter*, *Sphingomonas*

The orders *Rhodobacterales* and *Rhodospirillales* (Figure 16.3) contain metabolically diverse organisms that have been discussed previously, including purple nonsulfur bacteria (*Rhodobacter* and *Rhodospirillum*, ◀ Section 15.5), aerobic anoxygenic phototrophs (*Roseobacter*, ◀ Section 15.5), nitrogen-fixing bacteria (*Azospirillum*, ◀ Section 15.9), denitrifiers (*Paracoccus*, ◀ Section 15.10), and magnetotactic bacteria (*Magnetospirillum*, ◀ Section 15.20), among others.

The *Caulobacterales* are typically oligotrophic and strictly aerobic chemoorganotrophs. Species typically form prosthecae or stalks (◀ Section 15.18), and many species display asymmetric forms of cell division. The characteristic genus is *Caulobacter*, which has a characteristic life cycle that we have discussed previously (◀ Sections 8.8 and 15.18).

The *Sphingomonadales* include diverse aerobic and facultatively aerobic chemoorganotrophs as well as species of aerobic anoxygenic phototrophs (*Erythrobacter*) and a few obligate anaerobes. The characteristic genus is *Sphingomonas*, which consists of obligately aerobic and nutritionally versatile species. Sphingomonads are widespread in aquatic and terrestrial environments and are notable for their ability to metabolize a wide range of organic compounds including many aromatic compounds that are common environmental

contaminants (toluene, nonylphenol, dibenzo-*p*-dioxin, naphthalene, and anthracene, among others). Consequently, sphingomonads have been widely studied as potential agents of bioremediation (▶ Sections 22.4 and 22.5). These organisms are typically easy to cultivate and grow well on a variety of complex culture media.

- What are some ways in which *Wolbachia* species can affect insects? What evolutionary pressures have likely caused *Wolbachia* to lose the ability to make peptidoglycan?
- *Agrobacterium tumefaciens* has been reclassified into the genus *Rhizobium*. What mechanism underlies the distribution of genes for virulence or symbiosis among the species of this genus?

16.2 Betaproteobacteria

With about 500 described species, the *Betaproteobacteria* are the third largest class of *Proteobacteria* (Figure 16.1). The *Betaproteobacteria* contain an immense amount of functional diversity (Figure 16.2 and ◀ Figure 15.1), and many species in this group have already been considered in Chapter 15. A total of six orders of *Betaproteobacteria* have many characterized species: *Burkholderiales*, *Hydrogenophilales*, *Methylophilales*, *Neisseriales*, *Nitrosomonadales*, and *Rhodocyclales* (Figure 16.7), and we focus on these here.

Burkholderiales

KEY GENUS: *Burkholderia*

The *Burkholderiales* contain species with a wide range of metabolic and ecological characteristics. Species include strictly aerobic, facultatively aerobic, and obligately anaerobic chemoorganotrophs, anoxygenic

Figure 16.7 Major orders of *Proteobacteria* in the class *Betaproteobacteria*. The phylogenetic tree was constructed using 16S rRNA gene sequences from representative genera of *Betaproteobacteria*. Order names are shown in bold.

phototrophs, obligate and facultative chemolithotrophs, free-living nitrogen fixers, and pathogens of plants, animals, and humans.

Burkholderia is the type genus for the *Burkholderiales*. The genus *Burkholderia* includes diverse species of chemoorganotrophs with strictly respiratory metabolism. All species can grow aerobically, some also grow anaerobically with nitrate as the electron acceptor, and many strains are able to fix N_2 . The metabolic versatility of *Burkholderia* species with respect to organic compounds, and aromatic compounds in particular, has led to interest in their use in bioremediation (► Section 22.4). Certain strains of *Burkholderia* have also been shown to promote plant growth. However, many species are potentially pathogenic for plants or animals. One of the best known of the pathogenic species is *Burkholderia cepacia* (Figure 16.8).

B. cepacia is primarily a soil bacterium but also an opportunistic pathogen. Often found in the rhizosphere of plants, *B. cepacia* can produce both antifungal and anti-nematodal compounds, and thus its ability to colonize plant roots can provide disease protection and promote plant growth. However, *B. cepacia* is also known as a plant pathogen in certain circumstances, and it is a major cause of soft rot in onions. *B. cepacia* has also emerged as an opportunistic hospital-acquired infection in humans, as it is a hardy organism that is difficult to eradicate from the clinical setting. *B. cepacia* can form secondary lung infections in patients who are immunocompromised or have pneumonia or cystic fibrosis. The ability of *B. cepacia* to form biofilms in the lung and its natural resistance to many antibiotics has made this organism, along with *Pseudomonas aeruginosa*, particularly dangerous for patients with cystic fibrosis (◄ Section 8.10 and ► Section 20.4).

Rhodocyclales

KEY GENERA: *Rhodocyclus*, *Zoogloea*

Like the *Burkholderiales*, the order *Rhodocyclales* contains species with diverse metabolic and ecological characteristics. The type genus for the *Rhodocyclales* is *Rhodocyclus*, a purple nonsulfur bacterium (◄ Section 15.5). Like most purple nonsulfur bacteria, *Rhodocyclus* species grow best as photoheterotrophs but most can also grow as photoautotrophs with H_2 as electron acceptor. Species can also grow by respiration in darkness, but they are typically found in illuminated anoxic environments where organic matter is present.

Zoogloea is another important genus of the *Rhodocyclales*. *Zoogloea* species are aerobic chemoorganotrophs that are distinctive for producing a thick gelatinous capsule that binds cells together into a

complex matrix with branching, fingerlike projections. This gelatinous matrix can cause *flocculation*, the formation of macroscopic particles that settle out of solution. *Zoogloea ramigera* is of particular importance in aerobic wastewater treatment (► Section 22.6), where it degrades much of the organic carbon in the waste stream and promotes flocculation and settling, crucial steps in water purification.

Neisseriales

KEY GENERA: *Chromobacterium*, *Neisseria*

The order *Neisseriales* contains at least 29 genera of diverse chemoorganotrophs. The best-characterized species are in the genera *Neisseria* and *Chromobacterium*. Species of *Neisseria* are commonly isolated from animals, and some of them are pathogenic. *Neisseria* species are always cocci (Figure 16.9a). Some *Neisseria* are free-living saprophytes and reside in the oral cavity and other moist areas on the animal body. Others are serious pathogens, such as *Neisseria meningitidis*, which can cause a potentially fatal inflammation of the membranes lining the brain (meningitis, ► Section 31.5). We discuss the clinical microbiology of *Neisseria gonorrhoeae*—the causative agent of the sexually transmitted disease gonorrhea—in Section 31.5 and the pathogenesis of gonorrhea itself in Section 31.13.

Chromobacterium is a close phylogenetic relative of *Neisseria* but is rod-shaped in morphology. The best-known *Chromobacterium* species is *C. violaceum*, a purple-pigmented organism (Figure 16.9b) found in soil and water and occasionally in pus-forming wounds of humans and other animals. *C. violaceum* and a few other chromobacteria produce the purple pigment *violacein* (Figure 16.9b), a water-insoluble pigment with both antimicrobial and antioxidant properties. *Chromobacterium* is a facultative aerobe, growing fermentatively on sugars and aerobically on various carbon sources.

Hydrogenophilales, Methylophilales, and Nitrosomonadales

KEY GENERA: *Hydrogenophilus*, *Thiobacillus*, *Methylophilus*, *Nitrosomonas*

These three orders contain organisms that have fairly specialized metabolic capabilities including chemolithotrophs and methylophilic; most species are obligate aerobes and many are autotrophic. *Hydrogenophilus thermoluteolus* is an obligate aerobe that can grow as a chemolithotroph using H_2 as an electron donor for respiration

Figure 16.8 Colonies of *Burkholderia*. Photograph of colonies of *Burkholderia cepacia* on an agar plate.

(◀ Section 3.11) and the Calvin cycle to fix CO₂. This species is a facultative chemolithotroph but can also grow as a chemoorganotroph on simple carbon sources. *Thiobacillus* is another important genus of *Hydrogenophilales*. Species of *Thiobacillus* can be chemoorganotrophs or chemolithotrophs. Chemolithotrophic species of *Thiobacillus* are sulfur bacteria (◀ Sections 14.7 and 15.12) that oxidize reduced sulfur compounds as electron donors and grow by aerobic respiration or denitrification (◀ Sections 14.11 and 15.10). Species of *Thiobacillus* can also fix CO₂ using the Calvin cycle and are commonly found in soils, sulfur springs, marine habitats, and other locales where reduced sulfur compounds are available.

The *Methylophilales* and *Nitrosomonadales* contain metabolically specialized organisms. *Methylophilus* species are obligate and facultative methylotrophs (◀ Section 14.16) that grow on methanol and other C₁ compounds, but not on CH₄. Facultative species can grow as chemoorganotrophs through aerobic respiration of simple sugars. The order *Nitrosomonadales* contains obligately chemolithotrophic ammonia-oxidizing bacteria, the key genera being *Nitrosomonas* and *Nitrospira* (◀ Section 15.10).

- List three genera of *Betaproteobacteria* that contain chemolithotrophic species.

16.3 Gammaproteobacteria: Enterobacteriales

KEY GENERA: *Enterobacter*, *Escherichia*, *Klebsiella*, *Proteus*, *Salmonella*, *Serratia*, *Shigella*

The *Gammaproteobacteria* are the largest and most diverse class of *Proteobacteria*, containing nearly half of all characterized species in the phylum. The class contains more than 1500 characterized species and at least 15 well-characterized orders (Figure 16.10, Figure 16.1b). Its species have diverse metabolic and ecological characteristics (Figure 16.2 and ▶ Figure 15.1) and include many well-known human pathogens. Species can be phototrophic (including the purple sulfur bacteria, ▶ Section 15.4), chemoorganotrophic, or chemolithotrophic, and can have either respiratory or fermentative metabolisms. Members of this group often grow rapidly in laboratory media and can be isolated from a wide diversity of habitats. In this section, we consider the *Enterobacteriales*, one of the largest and best-known orders within the *Gammaproteobacteria*.

The *Enterobacteriales*, commonly called the **enteric bacteria**, comprise a relatively homogeneous phylogenetic group within the *Gammaproteobacteria* and consist of facultatively aerobic, gram-negative, nonsporulating rods that are either nonmotile or motile by peritrichous flagella (Figure 16.11). The *oxidase test* and the *catalase test* are common assays used to characterize bacteria (▶ Section 29.3 and Figure 29.6), and these tests can be used to discriminate enteric bacteria from many other *Gammaproteobacteria*. The oxidase test is an assay for the presence of cytochrome *c* oxidase, an enzyme present in many respiring bacteria. The catalase test assays for the enzyme catalase, which detoxifies hydrogen peroxide and is commonly found in bacteria able to grow in the presence of oxygen (◀ Section 4.16 and

Figure 16.10 Major orders of *Proteobacteria* in the class *Gammaproteobacteria*. The phylogenetic tree was constructed using 16S rRNA gene sequences from representative genera of *Gammaproteobacteria*. Order names are shown in bold.

Figure 4.32). Enteric bacteria are oxidase-negative and catalase-positive. They also produce acid from glucose and reduce nitrate but only to nitrite. Enteric bacteria have relatively simple nutritional requirements and ferment sugars to a variety of end products.

Among the enteric bacteria are many species pathogenic to humans, other animals, or plants, as well as other species of industrial importance. *Escherichia coli*, the best known of all organisms, is the classic enteric bacterium. Because of the medical importance of many enteric bacteria, an extremely large number have been characterized, and numerous genera and species have been defined, largely for ease in identification purposes in clinical microbiology. However, because enteric bacteria are genetically very closely related, their positive identification often presents considerable difficulty. In clinical laboratories, identification is typically based on the combined analysis of a large number of diagnostic tests carried out using miniaturized rapid diagnostic media kits along with immunological and genomic analyses to identify signature proteins or genes of particular species (Chapter 29).

Fermentation Patterns in Enteric Bacteria

One major taxonomic characteristic separating the various genera of enteric bacteria is the type and proportion of fermentation products generated from the fermentation of glucose. Two broad patterns are recognized, the *mixed-acid fermentation* and the *2,3-butanediol fermentation* (Figure 16.12).

Figure 16.11 A butanediol-producing enteric bacterium. Electron micrograph of a shadow-cast preparation of a cell of the butanediol-producing bacterium *Erwinia carotovora*. The cell is about 0.8 μm wide. Note the peritrichously arranged flagella (arrows), typical of enteric bacteria.

In the mixed-acid fermentation, three acids are formed in significant amounts: acetic, lactic, and succinic. Ethanol, CO₂, and H₂ are also formed, but not butanediol. In the butanediol fermentation, smaller amounts of acids are formed, and butanediol, ethanol, CO₂, and H₂ are the main products (◀ Figure 14.45). As a result of mixed-acid fermentation, equal amounts of CO₂ and H₂ are produced, whereas in the butanediol fermentation, considerably more CO₂ than H₂ is produced. This is because mixed-acid fermenters produce CO₂ only from formic acid by means of the enzyme formate hydrogenlyase:

This reaction results in equal amounts of CO₂ and H₂. The butanediol fermenters also produce CO₂ and H₂ from formic acid, but they produce two additional molecules of CO₂ during the formation of each molecule of butanediol (Figure 16.12b). Butanediol fermentation is characteristic of *Enterobacter*, *Klebsiella*, *Erwinia*, and *Serratia*, whereas mixed-acid fermentation is observed in *Escherichia*, *Salmonella*, *Shigella*, *Citrobacter*, *Proteus*, and *Yersinia*.

Mixed-Acid Fermenters: *Escherichia*, *Salmonella*, *Shigella*, and *Proteus*

Species of *Escherichia* are almost universal inhabitants of the intestinal tract of humans and other warm-blooded animals, although they are by no means the dominant organisms in this habitat. *Escherichia* may play a nutritional role in the intestinal tract by synthesizing vitamins, particularly vitamin K. As a facultative aerobe, this organism probably also helps consume O₂, thus rendering the large intestine anoxic. Wild-type *Escherichia* strains rarely show any growth-factor requirements and are able to grow on a wide variety of carbon and energy sources such as sugars, amino acids, and organic acids.

Some strains of *Escherichia* are pathogenic and have been implicated in diarrheal diseases, especially in infants; diarrheal diseases are a major public health problem in developing countries (▶ Sections 33.1, 33.2, 33.7, and 33.11). *Escherichia* is also a major cause of urinary tract infections in women. Enteropathogenic *E. coli* strains are becoming more frequently implicated in gastrointestinal infections and generalized fevers. Some strains, such as enterohemorrhagic *E. coli*, an important representative of which is strain O157:H7, can cause sporadic outbreaks of severe foodborne disease. Infection occurs primarily through consumption of contaminated

(a) Mixed-acid fermentation (for example, *Escherichia coli*)

(b) Butanediol fermentation (for example, *Enterobacter aerogenes*)

Figure 16.12 Enteric fermentations. Distinction between (a) mixed-acid and (b) butanediol fermentation in enteric bacteria (see also Figure 14.45). The solid arrows indicate reactions leading to major products. Dashed arrows indicate minor products. (a) The photo shows the production of acid (yellow) and gas (in the inverted Durham tube) in a culture of *Escherichia coli* carrying out a mixed-acid fermentation (purple tube was uninoculated). (b) The photo shows the pink-red color in the Voges-Proskauer (VP) test, which indicates butanediol production, following growth of *Enterobacter aerogenes*. The left (yellow) tube was not inoculated. Note that the mixed-acid fermentation produces less CO₂ but more acid products from glucose than does the butanediol fermentation.

foods, such as raw or undercooked ground beef, unpasteurized milk, or contaminated water. In a small percentage of cases, *E. coli* O157:H7 causes a life-threatening complication related to its production of a potent enterotoxin.

Salmonella and *Escherichia* are quite closely related. However, in contrast to *Escherichia*, species of *Salmonella* are almost always pathogenic, either to humans or to other warm-blooded animals (*Salmonella* is also found in the intestines of cold-blooded animals, such as turtles and lizards). In humans the most common diseases caused by salmonellas are typhoid fever and gastroenteritis (▶ Sections 33.5 and 33.10). The shigellas are also genetically very closely related to *Escherichia*. Genomic analyses strongly suggest that *Shigella* and *Escherichia* have exchanged a significant number of genes by horizontal gene flow. In contrast to most *Escherichia*, however, species of *Shigella* are typically pathogenic to humans, causing a rather severe gastroenteritis called *bacillary dysentery*. *Shigella dysenteriae*, transmitted by food- and waterborne routes, is a good example of this. The bacterium, which contains endotoxin,

invades intestinal epithelial cells, where it excretes a neurotoxin that causes acute gastrointestinal distress.

The genus *Proteus* typically contains highly motile cells (Figure 16.13) that produce the enzyme *urease*. Unlike *Salmonella* and *Shigella*, *Proteus* shows only a distant relationship to *E. coli*. *Proteus* is a frequent cause of urinary tract infections in humans and probably benefits in this regard from its ready ability to degrade urea by *urease*. Because of the rapid motility of *Proteus* cells, colonies growing on agar plates often exhibit a characteristic *swarming* phenotype (Figure 16.13b). Cells at the edge of the growing colony are more rapidly motile than those in the center of the colony. The former move a short distance away from the colony in a mass and then undergo a reduction in motility, settle down, and divide, forming a new population of motile cells that again swarm. As a result, the mature colony appears as a series of concentric rings, with higher concentrations of cells alternating with lower concentrations (Figure 16.13b).

Butanediol Fermenters: *Enterobacter*, *Klebsiella*, and *Serratia*

The butanediol fermenters are genetically more closely related to each other than to the mixed-acid fermenters, a finding that is in agreement with the observed physiological differences (Figure 16.12).

Figure 16.13 Swarming in *Proteus*. (a) Cells of *Proteus mirabilis* stained with a flagella stain; the peritrichous flagella of each cell form into a bundle to rotate in synchrony. (b) Photo of a swarming colony of *Proteus vulgaris*. Note the concentric rings.

John Vercillo and Cheryl Broadie

Figure 16.14 Colonies of *Serratia marcescens*. The orange-red pigmentation is due to the pyrrole-containing pigment prodigiosin.

Enterobacter aerogenes is a common species in water and sewage as well as the intestinal tract of warm-blooded animals and is an occasional cause of urinary tract infections. One species of *Klebsiella*, *K. pneumoniae*, occasionally causes pneumonia in humans, but *klebsiellas* are most commonly found in soil and water. Most *Klebsiella* strains also fix nitrogen (◀ Sections 3.12 and 15.9), a property not characteristic of other enteric bacteria.

The genus *Serratia* forms a series of red pyrrole-containing pigments called *prodigiosins* (Figure 16.14). Prodigiosin is produced in stationary phase as a secondary metabolite and is of interest because it contains the pyrrole ring also found in the pigments for energy transfer: porphyrins, chlorophylls, bacteriochlorophylls, and phycobilins (◀ Sections 14.3–14.5). However, it is unclear if prodigiosin plays any role in energy transfer, and its exact function is unknown. Species of *Serratia* can be isolated from water and soil as well as from the gut of various insects and vertebrates and occasionally from the intestines of humans. *Serratia marcescens* is also a human pathogen that can cause infections in many body sites. It has been implicated in infections caused by some invasive medical procedures and is an occasional contaminant in intravenous fluids.

- What characteristics would you use to distinguish between *Escherichia coli* and *Klebsiella pneumoniae*?

16.4 Gammaproteobacteria: Pseudomonadales and Vibrionales

KEY GENERA: *Aliivibrio*, *Pseudomonas*, *Vibrio*

The phylogenetic and metabolic diversity of the Gammaproteobacteria is remarkable (Figure 16.2 and ◀ Figure 15.1), making it difficult to select any particular species as characteristic of the class. We focus here on the Pseudomonadales and Vibrionales, since these groups (along with the Enterobacteriales) represent some of the most commonly encountered orders of Gammaproteobacteria (Figure 16.10).

Pseudomonadales

The *Pseudomonadales* contain exclusively chemoorganotrophs that carry out respiratory metabolisms. All species can grow as aerobes and are typically oxidase- and catalase-positive, but some are also capable of anaerobic respiration with nitrate as the electron acceptor. Most species are able to use a wide diversity of organic compounds as sources of carbon and energy for growth. These organisms are ubiquitous in soil and aquatic systems, and many species cause diseases of plants and animals, including humans. The term **pseudomonad** is often used to describe any gram-negative, polarly flagellated, aerobic rod that is able to use diverse carbon sources. Pseudomonads can be found in several different groups of *Proteobacteria*, but here we consider only those organisms in the order *Pseudomonadales*. The type genus for this order is *Pseudomonas*.

Several species of *Pseudomonas* are pathogenic. Among these, *Pseudomonas aeruginosa* (Figure 16.15) is frequently associated with infections of the urinary and respiratory tracts in humans. *P. aeruginosa* is not an obligate pathogen. Instead, the organism is an opportunist, initiating infections in individuals with weakened immune systems. *P. aeruginosa* is a model organism used to study the development of microbial biofilms (◀ Sections 4.9 and 8.10). Due to its ability to readily colonize surfaces, *P. aeruginosa* is a common cause of hospital-acquired (nosocomial) infections from catheterizations, tracheostomies, lumbar punctures, and intravenous infusions. *P. aeruginosa* is also a common pathogen in patients receiving treatment for severe burns or other traumatic skin damage; it often infects patients undergoing prolonged treatment with immunosuppressive agents; and it often colonizes the lungs of people with cystic fibrosis. In addition to localized infections, *P. aeruginosa* can also cause systemic infections, usually in individuals who have experienced extensive skin damage.

P. aeruginosa is naturally resistant to many widely used antibiotics, so treatment of infections is often difficult. Resistance is typically due to a resistance transfer plasmid (R plasmid) (◀ Section 6.2 and ▶ Section 28.7), which is a plasmid whose genes encode proteins that detoxify various antibiotics or pump them out of the cell. Resistance to antibiotics is further enhanced by biofilm growth (◀ Section 8.10). Polymyxin, an antibiotic not ordinarily used in human therapy because of its toxicity, is effective against *P. aeruginosa* and is used in critical medical situations.

Certain species of *Pseudomonas*, such as *Pseudomonas syringae*, are well-known plant pathogens (phytopathogens). Phytopathogens frequently inhabit nonhost plants (in which disease symptoms are inapparent) and from there become transmitted to host plants and

initiate infection. Disease symptoms vary considerably, depending on the particular phytopathogen and host plant. The pathogen releases plant toxins, lytic enzymes, plant growth factors, and other substances that destroy or distort plant tissue, releasing nutrients for use by the bacterium. In many cases the disease symptoms help identify the phytopathogen. Thus, *Pseudomonas syringae* is typically isolated from leaves showing chlorotic (yellowing) lesions, whereas *Pseudomonas marginalis*, a “soft-rot” pathogen, infects stems and shoots but rarely leaves.

Vibrionales

The *Vibrionales* contain facultatively aerobic rods and curved rods that employ a fermentative metabolism. One key difference between the *Vibrio* group and enteric bacteria is that *Vibrio* are oxidase-positive whereas enteric bacteria are oxidase-negative. Although *Pseudomonas* species are also oxidase-positive, they are not fermentative and so are clearly distinct from *Vibrio* species. The best-known genera in this group are *Vibrio*, *Aliivibrio*, and *Photobacterium*, which contain several species that are bioluminescent (▶ Section 23.10).

Most vibrios and related bacteria are aquatic, being found in marine, brackish, or freshwater habitats. *Vibrio cholerae* is the cause of the disease cholera in humans (▶ Sections 30.8 and 33.3); the organism does not normally cause disease in other hosts. Cholera is one of the most common human infectious diseases in developing countries and is transmitted almost exclusively via water.

Vibrio parahaemolyticus inhabits the marine environment and is a major cause of gastroenteritis in Japan, where raw fish is widely consumed; the organism has also been implicated in outbreaks of gastroenteritis in other parts of the world, including the United States. *V. parahaemolyticus* can be isolated from seawater itself or from shellfish and crustaceans, and its primary habitat is probably marine animals, with humans being an accidental host.

- What major characteristic could be used to differentiate strains of *Pseudomonas* from those of *Vibrio*?

16.5 Deltaproteobacteria and Epsilonproteobacteria

These classes of *Proteobacteria* contain fewer species and less functional diversity than we have encountered in the *Alpha*-, *Beta*-, and *Gamma**proteobacteria* (Figure 16.2 and ◀ Figure 15.1). The *Deltaproteobacteria* are primarily sulfate- and sulfur-reducing bacteria (◀ Sections 14.12, 15.11), dissimilative iron-reducers (◀ Section 15.13), and bacterial predators (◀ Section 15.16). *Epsilonproteobacteria*, by contrast, contain many species that oxidize the H_2S produced by the sulfate and sulfur reducers (◀ Sections 14.7, 15.12). The final class of *Proteobacteria*, the *Zetaproteobacteria*, contains only one characterized species (the iron oxidizer *Mariprofundus ferrooxydans*) and was considered earlier (◀ Section 15.14).

Figure 16.15 Cell morphology of pseudomonads. Shadow-cast transmission electron micrograph of a *Pseudomonas* cell. The cell measures about 1 μm in diameter.

Deltaproteobacteria

KEY GENERA: *Bdellovibrio*, *Myxococcus*, *Desulfovibrio*, *Geobacter*, *Syntrophobacter*

Eight orders have been well characterized within the *Deltaproteobacteria* (Figure 16.16). The *Myxococcales* and *Bdellovibrionales* contain notable genera of bacterial predators (◀ Section 15.16). In contrast, the *Desulfuromonadales* contains diverse species of metal- and sulfur-reducing genera such as *Geobacter* (◀ Sections 14.13, 15.13). Indeed, like the *Desulfuromonadales*, many genera from the *Deltaproteobacteria* are associated with the reduction of sulfur compounds.

The largest and most common order containing sulfate reducers is the *Desulfovibrionales*. These organisms are readily cultivated from marine sediments and nutrient-rich anoxic environments that contain sulfate. Species of *Desulfovibrionales* are typically incomplete oxidizers (◀ Section 15.11). All use sulfate as the terminal electron acceptor, and all require small organic compounds such as lactate as a source of carbon and energy for growth. Species within the orders *Desulfobacterales* and *Desulfarculales* also typically reduce sulfate; however, in contrast to the *Desulfovibrionales*, these species can be complete or incomplete acetate oxidizers (◀ Section 15.11). In addition to sulfate, some species in these three orders can also reduce sulfite, thio-sulfate, or nitrate, and some are capable of certain fermentations.

The final order containing sulfate reducers is the *Syntrophobacterales*. Some but not all species of the *Syntrophobacterales* are able to reduce sulfate. In nature, however, species of *Syntrophobacterales* primarily interact with H₂-consuming bacteria in a metabolic partnership called *syntrophy* (◀ Section 14.22). For example, syntrophic species such as *Syntrophobacter wolinii* oxidize propionate, producing acetate, CO₂, and H₂. However, such growth is only possible when

a H₂-consuming partner is present. If sulfate is present, *S. wolinii* can grow as a sulfate reducer without the need for a partner. *S. wolinii* can also grow without a partner organism by fermenting pyruvate, fumarate, or malate.

Epsilonproteobacteria

KEY GENERA: *Campylobacter*, *Helicobacter*

The *Epsilonproteobacteria* (Figure 16.16) were initially defined by pathogenic species of the genera *Campylobacter* and *Helicobacter*. While these pathogenic species remain the best characterized in the phylum, environmental studies of marine and terrestrial microbial habitats have shown that a diversity of *Epsilonproteobacteria* exist in nature. Nearly all of these environmental *Epsilonproteobacteria* metabolize sulfur compounds in one way or another, and chemolithotrophs and autotrophs are common. We will see that many *Epsilonproteobacteria* are associated with hosts as either pathogens or symbionts.

Campylobacter and Helicobacter

These two genera of *Epsilonproteobacteria* share a number of characteristics. *Campylobacter* and *Helicobacter* species are gram-negative, oxidase- and catalase-positive, motile spirilla, and most species are pathogenic to humans or other animals. These organisms are also microaerophilic (◀ Section 4.16) and must therefore be cultured from clinical specimens at low (3–15%) O₂ and high (3–10%) CO₂.

Campylobacter species, over a dozen of which have been described, cause acute gastroenteritis that typically results in a bloody diarrhea. Pathogenesis is due to several factors, including an enterotoxin that is related to cholera toxin. *Helicobacter pylori*, also a pathogen, causes both chronic and acute gastritis, leading to the formation of peptic ulcers. We consider these diseases, including their modes of transmission and clinical symptoms, in more detail in Section 31.10.

Sulfur-Metabolizing Epsilonproteobacteria

Through environmental sequencing studies (▶ Sections 19.6 and 19.8) and ongoing cultivation efforts, species of *Epsilonproteobacteria* are now recognized as ubiquitous in marine and terrestrial environments. These microbes are particularly abundant where sulfur-cycling activities are ongoing, particularly in deep-sea hydrothermal vent habitats and marine sediments where sulfide-rich and oxygenated waters mix (▶ Sections 20.15 and 20.16). Thermophilic species are common in this class of bacteria, contributing to their prevalence at hydrothermal systems (▶ Section 20.16). Chemolithotrophy and autotrophy (by the reverse TCA cycle, ◀ Section 14.2) are also widespread among *Epsilonproteobacteria*. Many species are able to grow aerobically or anaerobically (using oxidized nitrogen or sulfur compounds as electron acceptor) while using inorganic electron donors such as reduced sulfur compounds or H₂. *Epsilonproteobacteria* are especially abundant attached to surfaces at the oxic–anoxic interfaces in sulfur-rich environments and play major roles in the oxidation of sulfur compounds in nature.

The ability of *Epsilonproteobacteria* to fix CO₂ is of particular importance to many animals that live in sulfur-rich environments. For example, *Epsilonproteobacteria* can account for up to 85% of the microbial biomass growing on hydrothermal vent chimneys (▶ Section 20.16 and Figure 20.44). In addition,

Figure 16.16 Major orders of *Proteobacteria* in the classes *Deltaproteobacteria* and *Epsilonproteobacteria*. The phylogenetic tree was constructed using 16S rRNA gene sequences from representative genera in the *Delta*- and *Epsilonproteobacteria*. Order names are shown in bold.

Epsilonproteobacteria grow as ectosymbionts and endosymbionts of many animals such as oligochaete and polychaete worms, snails, and even shrimp. These symbionts can play two roles for the host, both providing a source of nutrition and helping to detoxify H_2S that would otherwise be deleterious to the hosts (► Section 23.11). Further exploration of the phylogeny, metabolic activities, and ecological roles of *Epsilonproteobacteria* will likely uncover exciting new aspects of prokaryotic diversity.

Check Your Understanding

- What four metabolic traits are most common in species of *Deltaproteobacteria*?
- What are some characteristic metabolic traits you would expect to find in *Epsilonproteobacteria* living at a hydrothermal vent?

II • Firmicutes, Tenericutes, and Actinobacteria

The *Firmicutes* and *Actinobacteria* contain gram-positive Bacteria and include many well-characterized bacteria. The *Tenericutes* include species such as *Mycoplasma* that have lost the ability to make peptidoglycan and a cell wall of any kind.

We continue our tour of phylogenetic bacterial diversity with the gram-positive bacteria of the phyla *Actinobacteria* and *Firmicutes*, and the closely related phylum *Tenericutes* (Figure 16.17). These three phyla contain nearly half of all characterized species of Bacteria (Figure 16.1b).

The *Actinobacteria* include the actinomycetes, a huge group of primarily filamentous soil bacteria. One distinguishing feature of the *Actinobacteria* is that their genomic DNA typically has a high frequency of GC base pairs, and as a result they are also called the **high G + C gram-positive bacteria**. The *Tenericutes* include cells that lack a cell wall, and the *Firmicutes* include the endospore-forming bacteria, lactic acid bacteria, and several other groups. In contrast to the *Actinobacteria*, the genomes of *Firmicutes* generally have a low GC content, and as a result, they are also called the **low G + C gram-positive bacteria**.

We begin by examining *Firmicutes* that do not form endospores.

16.6 Firmicutes: Lactobacillales

KEY GENERA: *Lactobacillus*, *Streptococcus*

The order *Lactobacillales* contains the **lactic acid bacteria**, fermentative organisms that produce lactic acid as a major end product of metabolism. These organisms are used widely in food production and preservation (◄ Section 1.6). Lactic acid bacteria are nonsporulating, oxidase- and catalase-negative rods or cocci that show an exclusively fermentative metabolism. All lactic acid bacteria produce lactic acid as a major or sole fermentation product (◄ Sections 3.7, 14.18). Members of this group lack porphyrins and cytochromes; thus they do not carry out oxidative phosphorylation and obtain energy only by substrate-level phosphorylation. However, unlike many anaerobes, most lactic acid bacteria are not sensitive to oxygen (O_2) and can grow in its presence; thus they are called *aerotolerant anaerobes* (◄ Section 4.16).

Figure 16.17 Major orders of gram-positive bacteria and relatives. The phylogenetic tree was constructed from 16S rRNA gene sequences of representative genera of *Actinobacteria*, *Firmicutes*, and *Tenericutes*. Order names are shown in bold.

Most lactic acid bacteria obtain energy only from the metabolism of sugars and therefore are usually restricted to habitats in which sugars are present. They typically have limited biosynthetic abilities, and their complex nutritional requirements include needs for amino acids, vitamins, purines, and pyrimidines (for example, ◄ Table 4.2 for *Leuconostoc mesenteroides*). One important difference between subgroups of the lactic acid bacteria lies in the pattern of products formed from the fermentation of sugars. One group, called **homofermentative**, produces a single fermentation product, *lactic acid*. The other group, called **heterofermentative**, produces other products, mainly ethanol and CO_2 , as well as lactate (◄ Section 14.18 and Figure 14.44).

Lactobacillus

Lactobacilli are typically rod-shaped and grow in chains, varying from long and slender to short, bent rods (Figure 16.18), and most are homofermentative. Lactobacilli are common in dairy products, and some strains are used in the preparation of fermented milk products. For instance, *Lactobacillus acidophilus* (Figure 16.18a) is used in the production of acidophilus milk; *Lactobacillus delbrueckii* (Figure 16.18c) is used in the preparation of yogurt; and other species are used in the production of sauerkraut, silage, and pickles (► Section 33.6).

Figure 16.18 *Lactobacillus* species. (a) *Lactobacillus acidophilus*, phase-contrast. Cells are about $0.75\ \mu\text{m}$ wide. (b) *Lactobacillus brevis*, transmission electron micrograph. Cells measure about $0.8 \times 2\ \mu\text{m}$. (c) *Lactobacillus delbrueckii*, scanning electron micrograph. Cells are about $0.7\ \mu\text{m}$ in diameter.

Lactobacilli are typically more resistant to acidic conditions than are other lactic acid bacteria and are able to grow well at pH values as low as 4. Because of this, they can be selectively enriched from dairy products and fermenting plant material on acidic carbohydrate-containing media. The acid resistance of the lactobacilli enables them to continue growing during natural lactic fermentations, even when the pH value has dropped too low for other lactic acid bacteria to grow. The lactobacilli are therefore typically responsible for the final stages of most lactic acid fermentations. They are rarely, if ever, pathogenic.

Streptococcus and Other Cocci

The genera *Lactococcus* and *Streptococcus* (Figure 16.19) contain homofermentative species of coccoid-shaped lactic acid bacteria with quite distinct habitats and activities that are of considerable practical importance to humans. Some species are pathogenic to humans and animals (► Section 31.2). *Streptococcus* species (Figure 16.19a) have a characteristic cell morphology of cocci in chains or tetrads and so are readily resolved from the rod-shaped lactobacilli. As producers of lactic acid, other streptococci play important roles in the production of buttermilk, silage, and other fermented products (► Section 33.6), and certain species play a major role in the formation of dental caries (► Sections 24.3 and 25.1).

Figure 16.19 Gram-positive cocci. (a) *Streptococcus* sp., scanning electron micrograph. (b) *Lactococcus lactis*, phase-contrast micrograph. Cells in both photos are $0.5\text{--}1\ \mu\text{m}$ in diameter. (c) Colony of *Leuconostoc mesenteroides* showing the extensive dextran slime produced by cells grown on sucrose.

There are several other genera of homofermentative cocci. The genus *Lactococcus* (Figure 16.19b) contains those streptococci of dairy significance, whereas the genus *Enterococcus* includes streptococci that are primarily of fecal origin and can be human pathogens. Species of the genera *Peptococcus* and *Peptostreptococcus* are obligate anaerobes that ferment proteins rather than sugars.

Streptococci have been divided into two groups of related species: the *pyogenes* subgroup, characterized by *Streptococcus pyogenes*, the cause of strep throat (► Section 31.2), and the *viridans* subgroup, characterized by *Streptococcus mutans*, the major cause of dental caries (► Sections 24.3 and 25.1). Hemolysis on blood agar is of considerable importance in the subdivision of the genus into species. For example, species that produce the virulence factors streptolysin O or S form colonies surrounded by a large zone of complete red blood cell hemolysis when plated on blood agar, a condition called β -hemolysis (► Figures 25.17a, 31.4b, and 31.8). β -hemolysis is diagnostic for streptococci in the *pyogenes* subgroup. In contrast, streptococci in the *viridans* subgroup cause incomplete hemolysis on blood agar, a condition that leads to greening of the agar under colonies. Streptococci are also divided into immunological groups (designated by the letters A, B, C, F, G), based on the presence of specific carbohydrate antigens (antigens are substances that elicit an immune response). Those β -hemolytic streptococci found in humans usually contain the group A antigen, whereas enterococci contain the group D antigen.

Heterofermentative lactococci reside in the genus *Leuconostoc*. Strains of *Leuconostoc* also produce the flavoring ingredients diacetyl and acetoin from the catabolism of citrate; they have been used as starter cultures in dairy fermentations. Some strains of *Leuconostoc* produce large amounts of glucose or fructose polysaccharide slimes, especially when cultured on sucrose as the carbon and energy source (Figure 16.19c), and some of these polymers have found medical use as plasma extenders in blood transfusions.

Check Your Understanding

- How do heterofermentative and homofermentative bacteria differ physiologically?
- How can *Streptococcus pyogenes* be distinguished from *Streptococcus mutans*?

16.7 Firmicutes: Nonsporulating Bacillales and Clostridiales

KEY GENERA: *Listeria*, *Staphylococcus*, *Sarcina*

Firmicutes that form endospores reside in the orders Bacillales and Clostridiales. However, numerous Bacillales and Clostridiales are unable to form endospores, and we consider some of these here.

Listeria

The order Bacillales typically contains aerobic and facultatively aerobic chemoorganotrophs. Members of this group are widespread and particularly common in soils. For example, *Listeria* is found widely in soils and is an opportunistic pathogen and a common cause of foodborne illness. *Listeria* are gram-positive, catalase-positive, rod-shaped, facultatively aerobic chemoorganotrophs. Although several species of *Listeria* are known, the species *Listeria monocytogenes* is most noteworthy because it causes a major foodborne illness, *listeriosis* (► Section 33.13). The organism is transmitted in contaminated, usually ready-to-eat foods such as cheese and sausages and can cause anything from a mild illness to a fatal form of meningitis. Species of *Listeria* often grow well at low temperatures, allowing growth in refrigerated foods.

Staphylococcus

Staphylococcus (Figure 16.20) is a facultative aerobe that shows a typical respiratory metabolism but can also grow fermentatively. Cells typically grow in clusters and produce acid from glucose both aerobically and anaerobically. *Staphylococcus* species are catalase-positive, and this permits their distinction from *Streptococcus* and some other genera of lactic acid bacteria. Staphylococci are relatively resistant to reduced water potential and tolerate drying and high salt (NaCl) fairly well. Their ability to grow in media containing salt provides a selective means for isolation. For example, if an appropriate inoculum such as a skin swab, dry soil, or room dust is spread on a rich-medium agar plate containing 7.5% NaCl and the plate is incubated aerobically, gram-positive cocci often form the predominant colonies. Many species are pigmented, and this provides an additional aid in selecting gram-positive cocci.

Staphylococci are common commensals and parasites of humans and animals, and they occasionally cause serious infections. In

Figure 16.20 *Staphylococcus*. (a) Scanning electron micrograph of typical *Staphylococcus aureus* cells, showing the irregular arrangement of the cell clusters. Individual cells are about 0.8 μm in diameter. (b) Transmission electron micrograph of a dividing cell of *S. aureus*. Note the thick gram-positive cell wall.

Figure 16.21 *Sarcina*. (a) Phase-contrast photomicrograph of cells of a typical gram-positive coccus *Sarcina*. A single cell is about 2 μm in diameter. (b) Electron micrograph of a thin section from *Sarcina ventriculi*. The outermost layer of the cell consists of cellulose.

humans, there are two major species, *Staphylococcus epidermidis*, a nonpigmented, nonpathogenic organism usually found on the skin or mucous membranes, and *Staphylococcus aureus* (Figure 16.20), a yellow-pigmented species that is most commonly associated with pathological conditions including boils, pimples, pneumonia, osteomyelitis, meningitis, and arthritis. Some *S. aureus* strains are resistant to multiple antibiotics (so-called MRSA strains) and are fierce pathogens that can cause extensive tissue damage (► Figure 31.9). We discuss the pathogenesis of MRSA and other strains of *S. aureus* and staphylococcal diseases in Sections 24.5, 29.2, and 31.9.

Sarcina

The genus *Sarcina* contains obligate anaerobes that are catalase-negative within the order Clostridiales. *Sarcina* species divide in three perpendicular planes to yield packets of eight or more cells and are notable for this morphology (Figure 16.21). *Sarcina* are also extremely acid-tolerant, being able to ferment sugars and grow in environments at a pH as low as 2. Cells of one species, *Sarcina ventriculi*, contain a thick, fibrous layer of cellulose surrounding the cell wall (Figure 16.21b). The cellulose layers of adjacent cells become attached, and this functions as a cementing material to hold together packets of *S. ventriculi* cells.

Sarcina species can be isolated from soil, mud, feces, and stomach contents. Because of its extreme acid tolerance, *S. ventriculi* is one of only a few bacteria that can inhabit and grow in the stomach of humans and other monogastric animals. Rapid growth of *S. ventriculi* is observed in the stomach of humans suffering from certain gastrointestinal disorders, such as pyloric ulcerations. These pathological conditions retard the flow of food to the intestine and often require surgery to correct.

Check Your Understanding

- How could species of *Staphylococcus* be differentiated from *Streptococcus*?
- What characteristics differentiate *Sarcina* from *Staphylococcus*?

Cells are about 1 μm wide. (c) *Clostridium bifermentans*, central endospores. Cells are about 1.2 μm wide. All are phase-contrast micrographs.

16.8 Firmicutes: Sporulating Bacillales and Clostridiales

KEY GENERA: *Bacillus*, *Clostridium*, *Sporosarcina*

All endospore-forming bacteria are gram-positive species of *Bacillales* or *Clostridiales*. The ability to form endospores evolved only once in a common ancestor of the *Bacillales*, *Clostridiales*, and *Lactobacillales* (Figure 16.17). However, many *Bacillales* and *Clostridiales* and the entire order *Lactobacillales* are unable to form endospores. The capacity to make endospores requires many genes (◀ Sections 2.8 and 8.6) and has not been acquired by horizontal gene transfer. It thus appears that the phylogenetic distribution of endospores has seen many cases where the capacity to form endospores has been lost during the course of evolution.

Endospore-forming bacteria are distinguished on the basis of cell morphology, shape and cellular position of the endospore (Figure 16.22), relationship to O_2 , and energy metabolism. The two genera about which most is known are *Bacillus*, species of which are aerobic or facultatively aerobic, and *Clostridium*, which contains species that are obligately anaerobic and fermentative. All endospore-forming bacteria are ecologically related because they are found in nature primarily in soil. Even those species that are pathogenic to humans or other animals are primarily saprophytic soil organisms and infect animals only incidentally. Indeed, the ability to produce endospores should be advantageous for a soil microorganism because soil is a highly variable environment in terms of nutrient levels, temperature, and water activity.

Endospore-forming bacteria can be selectively isolated from soil, food, dust, and other materials by heating the sample to 80°C for 10 min, a treatment that effectively kills vegetative cells while any endospores present remain viable. Streaking such heat-treated samples on plates of the appropriate medium and incubating either aerobically or anaerobically selectively yields species of *Bacillus* or *Clostridium*, respectively.

Bacillus and *Paenibacillus*

Species of *Bacillus* and *Paenibacillus* grow well on defined media containing any of a number of carbon sources. Many bacilli produce extracellular hydrolytic enzymes that break down complex polymers such as polysaccharides, nucleic acids, and lipids, permitting the organisms to use these products as carbon sources and electron donors. Many bacilli produce antibiotics, including bacitracin,

polymyxin, tyrocidine, gramicidin, and circulin. In most cases the antibiotics are released when the culture enters the stationary phase of growth and is committed to sporulation.

Several bacilli, most notably *Paenibacillus popilliae* and *Bacillus thuringiensis*, produce toxic insecticidal proteins. *P. popilliae* causes a fatal condition called milky disease in Japanese beetle larvae and larvae of closely related beetles of the family *Scarabaeidae*. *B. thuringiensis* causes a fatal disease of many different groups of insects. Both of these insect pathogens form a crystalline protein during sporulation called the *parasporal body*, which is deposited within the sporangium but outside the endospore proper (Figure 16.23). In

B. thuringiensis, the parasporal body is a protoxin that is converted to a toxin in the insect gut. The toxin binds to specific receptors in the intestinal epithelial cells of certain insects and induces pore formation that causes leakage of the host cell cytoplasm followed by lysis. Diverse strains of *B. thuringiensis* can make different types of toxin that have specificity for different groups of insects. Endospore preparations derived from *B. thuringiensis* and *P. popilliae* are commercially available as biological insecticides.

The *cry* genes that encode crystal proteins have been isolated from several *B. thuringiensis* strains. The genes for the *B. thuringiensis* crystal protein (known commercially as “Bt toxin”) have been introduced into genetically modified crops (e.g., maize, soybeans, and cotton) to render the plants resistant to insects. These genetically modified “Bt crops” are used widely around the world.

Clostridium

Clostridia lack a respiratory chain, unlike *Bacillus* species, and so they obtain ATP by substrate-level phosphorylation. Many anaerobic energy-yielding mechanisms are known in the clostridia (◀ Section 14.19). Indeed, the separation of the genus *Clostridium* into subgroups is based primarily on these properties and on the fermentable substrate used. A number of clostridia are *saccharolytic* and ferment sugars, producing butyric acid as a major end product. Some of these also produce acetone and butanol, such as *Clostridium pasteurianum*, which is also a vigorous nitrogen-fixing bacterium (◀ Sections 3.12 and 15.9).

Figure 16.23 The toxic parasporal crystal in the insect pathogen *Bacillus thuringiensis*. Electron micrograph of a thin section of a sporulating cell. The crystalline protein (Bt toxin) is toxic to certain insects by causing lysis of their intestinal cells.

One group of clostridia including the species *C. thermocellum*, *C. cellulolyticum*, and *C. cellulovorans* ferments cellulose with the formation of acids and alcohols. These species are likely the major organisms decomposing cellulose in anoxic environments such as the rumen and sediments. Cellulolytic clostridia possess *cellulosomes*, complex multienzyme structures found on the outer surface of the cell wall. The cellulosome binds insoluble cellulose and degrades it into soluble products that are transported into the cytoplasm and metabolized by the cell. This cellulosome mechanism is common to bacteria that are able to degrade cellulose anaerobically.

Another group of clostridia are *proteolytic* and conserve energy from the fermentation of amino acids. Some species ferment individual amino acids, but others ferment only amino acid pairs. The products of amino acid fermentation are typically acetate, butyrate, CO₂, and H₂. The coupled catabolism of an amino acid pair is called a *Stickland reaction*; for example, *Clostridium sporogenes* ferments glycine plus alanine. In the Stickland reaction, one amino acid functions as the electron donor and is oxidized, whereas the other is the electron acceptor and is reduced (◀ Figure 14.47). Many of the products of amino acid fermentation by clostridia are foul-smelling substances, and the odor that results from putrefaction is mainly the result of clostridial action. In addition to butyric acid, other odoriferous compounds produced are isobutyric acid, isovaleric acid, caproic acid, hydrogen sulfide, methyl mercaptan (from sulfur amino acids), cadaverine (from lysine), putrescine (from ornithine), and ammonia.

The main habitat of clostridia is the soil, where they live primarily in anoxic “pockets” made free of O₂ by the respiratory activities of facultative or obligately aerobic bacteria. In addition, a number of clostridia inhabit the anoxic environment of the mammalian intestinal tract. Several clostridia are capable of causing severe diseases in humans, as will be discussed in Sections 24.9, 30.7, 32.9 and 33.9. For example, botulism is caused by *Clostridium botulinum*, tetanus by *Clostridium tetani*, and gas gangrene by *Clostridium perfringens* and a number of other clostridia, both sugar and amino acid fermenters. These pathogenic clostridia seem in no way unusual metabolically but are distinct in that they produce specific toxins or, in those causing gas gangrene, a group of toxins. *C. perfringens* and related species can also cause gastroenteritis in humans and domestic animals (▶ Section 33.9), and botulism outbreaks are not uncommon in birds such as ducks and a variety of other animals.

Sporosarcina

The genus *Sporosarcina* (Figure 16.24) is unusual among endospore formers because cells are cocci instead of rods. *Sporosarcina* consists of strictly aerobic spherical to oval cells that divide in two or three perpendicular planes to form tetrads or packets of eight or more cells. The major species is *Sporosarcina ureae*. This bacterium can be enriched from soil by plating dilutions of a pasteurized soil sample on alkaline nutrient agar supplemented with 8% urea and incubating in air. Most soil bacteria are strongly inhibited by as little as 2% urea. However, *S. ureae* tolerates this, catabolizing urea to CO₂ and ammonia (NH₃), which dramatically raises the pH. *S. ureae* is remarkably alkaline-tolerant and can be grown in media up to pH 10, and this feature can be used to advantage in its enrichment from soil.

Figure 16.24 *Sporosarcina ureae*. Phase-contrast micrograph. A single cell is about 2 μm wide. Note bright refractile endospores. Most cell packets contain eight cells.

- What is the crystalline protein made by *Bacillus thuringiensis* and what is its significance to agriculture?

16.9 Tenericutes: The Mycoplasmas

KEY GENERA: *Mycoplasma*, *Spiroplasma*

The *Tenericutes*, which contain the single class *Mollicutes*, are bacteria that lack cell walls (*mollis* is Latin for “soft”) and are some of the smallest organisms known. This group is often called the *mycoplasmas* because *Mycoplasma*, a notable genus containing human pathogens, is the best-characterized genus in the phylum.

Although they do not stain gram-positively (because they lack cell walls), mycoplasmas are phylogenetically related to the *Firmicutes*. Mycoplasmas typically live within animal and plant hosts and this may eliminate the need for a gram-positive cell wall. These organisms also have small genomes (ranging in size from 0.6 to 2.2 megabase pairs [Mbp]), a characteristic common in obligate symbionts and intracellular pathogens (◀ Section 10.3 and ▶ Section 23.7).

Properties of Mycoplasmas

The absence of cell walls in mycoplasmas has been confirmed by electron microscopy and chemical analyses, which show that peptidoglycan is absent. Mycoplasmas resemble protoplasts (bacteria treated to remove their cell walls), but they are more resistant to osmotic lysis and are able to survive conditions under which protoplasts lyse. This ability to resist osmotic lysis is at least partially determined by the presence of sterols, which make the cytoplasmic membrane of mycoplasmas more stable than that of other bacteria. Indeed, some mycoplasmas require sterols in their growth media, and this sterol requirement can aid in the classification of mycoplasmas.

In addition to sterols, certain mycoplasmas contain compounds called *lipoglycans*. Lipoglycans are long-chain heteropolysaccharides covalently linked to membrane lipids and embedded in the cytoplasmic membrane of many mycoplasmas. Lipoglycans in some ways resemble the lipopolysaccharides in the outer membrane of gram-negative bacteria, except that they lack the lipid A backbone (◀ Section 2.4). Lipoglycans function to help stabilize the

Figure 16.25 *Mycoplasma mycoides*. Metal-shadowed transmission electron micrograph. Note the coccoid and hyphae-like elements. The average diameter of cells in chains is about 0.5 μm .

cytoplasmic membrane and have also been identified as facilitating attachment of mycoplasmas to cell surface receptors of animal cells.

Growth of Mycoplasmas

Mycoplasmas can be grown in the laboratory and are small and pleomorphic cells. A single culture may exhibit small coccoid elements; larger, swollen forms; and filamentous forms, often highly branched (Figure 16.25). The small coccoid elements (0.2–0.3 μm in size) are among the smallest of free-living cells. The mode of growth of mycoplasmas differs in liquid and agar cultures. On agar the organisms tend to grow so that they become embedded in the medium. These colonies show a characteristic “fried-egg” appearance consisting of a dense central core that penetrates downward into the agar, surrounded by a circular spreading area that is lighter in color (Figure 16.26). As would be expected of cells lacking cell walls, growth of *Mollicutes* is not inhibited by antibiotics that inhibit cell wall synthesis. However, mycoplasmas are as sensitive as most *Bacteria* to antibiotics whose targets are other than the cell wall.

Media for the culture of mycoplasmas are typically quite complex. For many species, growth is poor or absent even in complex yeast extract–peptone–beef heart infusion media. Fresh serum or ascitic fluid (peritoneal fluid) is needed as well to provide unsaturated fatty acids and sterols. Some mycoplasmas can be cultivated on relatively simple culture media, however, and even defined media have been developed for some species. Most mycoplasmas use carbohydrates as carbon and energy sources and require vitamins, amino acids, purines, and pyrimidines as growth factors.

Figure 16.26 Colonies of a *Mycoplasma* species on agar. Note the typical “fried-egg” appearance. The colonies are about 0.5 mm in diameter.

Figure 16.27 “Sex-ratio” spiroplasma from the hemolymph of the fly *Drosophila pseudoobscura*. Dark-field micrograph. Female flies infected with the sex-ratio spiroplasma bear only female progeny. Cells are about 0.15 μm in diameter.

Spiroplasma

The genus *Spiroplasma* consists of helical or spiral-shaped *Mollicutes*. Amazingly, although they lack a cell wall and flagella, spiroplasmas are motile by means of a rotary (screw) motion or a slow undulation. Intracellular fibrils that are thought to play a role in motility have been demonstrated. The organism has been isolated from ticks, the hemolymph (Figure 16.27) and gut of insects, vascular plant fluids and insects that feed on these fluids, and the surfaces of flowers and other plant parts. For example, *Spiroplasma citri* has been isolated from the leaves of citrus plants, where it causes a disease called citrus stubborn disease, and from corn plants suffering from corn stunt disease. A number of other mycoplasma-like organisms have been detected in diseased plants by electron microscopy, which indicates that a large group of plant-associated *Mollicutes* may exist. Some species of *Spiroplasma* are known that cause insect diseases, such as honeybee spiroplasmosis and lethargy disease of the beetle *Melolontha*.

Check Your Understanding

- Why do mycoplasmas need to have stronger cytoplasmic membranes than other bacteria?
- Motile spiroplasmas cannot contain a normal bacterial flagellum; why?

16.10 Actinobacteria: Coryneform and Propionic Acid Bacteria

KEY GENERA: *Arthrobacter*, *Corynebacterium*, *Propionibacterium*

The other major group of gram-positive bacteria is the *Actinobacteria*, which form their own phylum within the *Bacteria*. The *Actinobacteria* contain rod-shaped to filamentous and primarily aerobic bacteria that are common inhabitants of soil and plant materials. For the most part they are harmless commensals, species of *Mycobacterium* (for example, *Mycobacterium tuberculosis*) being notable exceptions. Some are of great economic value in either the production of antibiotics or certain fermented dairy products. While there are nine orders of *Actinobacteria*, the vast majority of species belong to the order *Actinomycetales* (Figure 16.17). We consider here the coryneform bacteria, species of *Actinomycetales* that have an unusual method of cell division, and the propionic acid bacteria, important agents in the ripening of Swiss cheese.

Figure 16.28 Snapping division in *Arthrobacter*. Phase-contrast micrograph of characteristic V-shaped cell groups in *Arthrobacter crystallopoietes* resulting from snapping division. Cells are about 0.9 μm in diameter.

Coryneform Bacteria

Coryneform bacteria are gram-positive, aerobic, nonmotile, rod-shaped organisms that form irregular-shaped, club-shaped, or V-shaped cell arrangements during growth. V-shaped cells arise as a result of an abrupt movement that occurs just after cell division, a process called *snapping division* (Figure 16.28). Snapping division occurs because the cell wall consists of two layers; only the inner layer participates in cross-wall formation, and so after the cross-wall is formed, the two daughter cells remain attached by the outer layer of the cell wall. Localized rupture of this outer layer on only one side of the cell results in a bending of the two cells away from the ruptured side (Figure 16.29) and thus development of V-shaped forms.

The main genera of coryneform bacteria are *Corynebacterium* and *Arthrobacter*. The genus *Corynebacterium* consists of an extremely diverse group of bacteria, including animal and plant pathogens and saprophytes. Some species, such as *Corynebacterium diphtheriae*, are pathogenic (diphtheria, ► Section 31.3). The genus *Arthrobacter*, consisting primarily of soil organisms, is distinguished from *Corynebacterium* on the basis of a developmental cycle during which it changes morphology between rod and coccus (Figure 16.30). *Corynebacterium* cells frequently have a swollen end, so they have a club-shaped appearance, whereas *Arthrobacter* species are less commonly club-shaped.

Along with the *Acidobacteria* (Section 16.21), species of *Arthrobacter* are among the most common of all soil bacteria. They are remarkably resistant to desiccation and starvation, despite the fact that they do not form spores or other resting cells. Arthrobacters are a heterogeneous group that have considerable nutritional versatility, and strains have been isolated that decompose herbicides, caffeine, nicotine, phenols, and other unusual organic compounds.

Figure 16.29 Cell division in *Arthrobacter*. Transmission electron micrograph of cell division in *Arthrobacter crystallopoietes*, illustrating how snapping division and V-shaped cell groups arise. (a) Before rupture of the outer cell wall layer (arrow). (b) After rupture of the outer layer on one side. Cells are 0.9–1 μm in diameter.

Propionic Acid Bacteria

The **propionic acid bacteria** (genus *Propionibacterium*) were first discovered in Swiss (Emmentaler) cheese, where their fermentative production of CO_2 produces the characteristic holes. In addition, the propionic acid they produce is at least partly responsible for the unique flavor of the cheese. The bacteria in this group are gram-positive anaerobes that ferment lactic acid, carbohydrates, and polyhydroxy alcohols, producing primarily propionic acid, acetic acid, and CO_2 (◄ Section 14.20).

The fermentation of lactate is of interest because lactate itself is a fermentation product of many bacteria (Section 16.6). The starter culture in Swiss cheese manufacture consists of a mixture of homofermentative streptococci and lactobacilli, plus propionic acid bacteria. The homofermentative organisms carry out the initial fermentation of lactose to lactic acid during formation of the curd

Figure 16.30 Stages in the life cycle of *Arthrobacter globiformis* as observed in slide culture. (a) Single coccoid element; (b–e) conversion to rod and growth of a microcolony consisting predominantly of rods; (f–g) conversion of rods to coccoid forms. Cells are about 0.9 μm in diameter.

(protein and fat). After the curd has been drained, the propionic acid bacteria develop rapidly. The eyes (or holes) characteristic of Swiss cheese are formed by the accumulation of CO₂, the gas diffusing through the curd and gathering at weak points. The propionic acid bacteria are thus able to obtain energy anaerobically from a product that other bacteria have produced by fermentation. This metabolic strategy is called a *secondary fermentation*.

Propionate is also formed in the fermentation of succinate by the bacterium *Propionigenium*. This organism is phylogenetically and ecologically unrelated to *Propionibacterium*, but energetic aspects of its fermentation are of considerable interest. We discussed the mechanism of the *Propionigenium* fermentation in Section 14.20.

Check Your Understanding

- What is snapping division and what organism exhibits it?
- What organism is involved in the production of Swiss cheese, and what products does it make that help to flavor the cheese and make the holes?

16.11 Actinobacteria: *Mycobacterium*

KEY GENUS: *Mycobacterium*

Mycobacteria are common in soils and most are harmless, but the genus *Mycobacterium* contains several notable human pathogens, chief among them *Mycobacterium tuberculosis*, the cause of tuberculosis (► Section 31.4). Species are rod-shaped bacteria that at some stage of their growth cycle possess the distinctive staining property called **acid-fastness**. This property is due to the presence of unique lipids called *mycolic acids*, found only in species of the genus *Mycobacterium*, on the surface of the mycobacterial cell. Mycolic acids are a group of complex branched-chain hydroxylated lipids (Figure 16.31a) covalently bound to peptidoglycan in the cell wall; the complex gives the cell surface a waxy, hydrophobic consistency.

Because of their waxy surface, mycobacteria do not stain well with Gram stain. A mixture of the red dye basic fuchsin and phenol is used in the acid-fast (Ziehl–Neelsen) stain. The stain is driven into the cells by slow heating, and the role of the phenol is to enhance penetration of the fuchsin into the lipids. After washing in distilled water, the preparation is decolorized with acid alcohol and

Figure 16.31 Acid-fast staining. Structure of (a) mycolic acid and (b) basic fuchsin, the dye used in the acid-fast stain. The fuchsin dye combines with mycolic acids in the cell wall via ionic bonds between COO[−] and NH₂⁺. Inset: Acid-fast stain of cells (red) of *Mycobacterium tuberculosis* present in a sputum sample from a tuberculosis patient.

counterstained with methylene blue. Cells of acid-fast organisms stain red (Figure 16.31 inset), whereas the background and non-acid-fast organisms appear blue (► Figure 31.15a).

Mycobacteria are somewhat pleomorphic and may undergo branching or even filamentous growth. However, in contrast to the filaments of the actinomycetes (Section 16.12), the filaments of the mycobacteria do not form a true mycelium. Mycobacteria can be separated into two major groups: slow-growing species (e.g., *M. tuberculosis*, *M. avium*, *M. bovis*, and *M. goodii*) and fast-growing species (e.g., *M. smegmatis*, *M. phlei*, *M. chelonae*, *M. parafortuitum*). *Mycobacterium tuberculosis* is a typical slow grower, and visible colonies are produced from dilute inoculum only after days to weeks of incubation. When growing on solid media, mycobacteria form tight, compact, often wrinkled colonies (Figure 16.32). This colony morphology is probably due to the high lipid content and hydrophobic nature of the cell surface, which facilitates cells sticking together.

For the most part, mycobacteria have relatively simple nutritional requirements. Most species can grow aerobically in a simple mineral-salts medium with ammonium as the nitrogen source and glycerol or acetate as the sole carbon source and electron donor. Growth of *M. tuberculosis* is more difficult and is stimulated by lipids and fatty acids. The virulence of *M. tuberculosis* cultures has been correlated with the formation of long, cordlike structures (Figure 16.32b) that

Figure 16.32 Characteristic colony morphology of mycobacteria. (a) *Mycobacterium tuberculosis*, showing the compact, wrinkled appearance of the colony. The colony is about 7 mm in diameter. (b) A colony of virulent *M. tuberculosis* at an early stage, showing the characteristic cordlike growth. Individual cells are about 0.5 μm in diameter. (See also the historic drawings of *M. tuberculosis* cells made by Robert Koch, Figure 1.35). (c) Colonies of *Mycobacterium avium* from a strain of this organism isolated as an opportunistic pathogen from an AIDS patient.

form as a result of side-to-side aggregation and intertwining of long chains of bacteria. Growth in cords reflects the presence of a characteristic glycolipid, the *cord factor*, on the cell surface (Figure 16.33). The pathogenesis of tuberculosis, along with the related mycobacterial disease leprosy, is discussed in Section 31.00.

Some mycobacteria produce yellow carotenoid pigments (Figure 16.32c), and pigmentation can aid in identification. Mycobacteria can either be nonpigmented (e.g., *M. tuberculosis*, *M. bovis*, *M. smegmatis*, *M. chelonae*); or can form pigment only when cultured in light, a property called *photochromogenesis* (e.g., *M. parafortuitum*); or can form pigment even when cultured in the dark, a property called *scotochromogenesis* (e.g., *M. gordonae*, *M. phlei*). Photochromogenesis is triggered by the blue region of the visible spectrum and is characterized by the photoinduction of one of the early enzymes in carotenoid biosynthesis. As with other carotenoid-containing bacteria, it is likely that carotenoids protect mycobacteria against oxidative damage from singlet oxygen (◀ Section 4.16).

Check Your Understanding

- What is mycolic acid, and what properties does this substance confer on mycobacteria?

16.12 Filamentous Actinobacteria: *Streptomyces* and Relatives

KEY GENERA: *Streptomyces*, *Actinomyces*, *Nocardia*

The **actinomycetes** are a large group of phylogenetically related, filamentous and aerobic gram-positive *Bacteria* common in soils. Many actinomycetes have a characteristic developmental cycle that culminates in the production of desiccation-resistant spores. Filaments elongate from their ends and form branching *hyphae*. Hyphal growth results in a network of filaments called a *mycelium* (Figure 16.34), analogous to that formed by filamentous fungi (▶ Section 18.9). When nutrients are depleted, the mycelium forms aerial hyphae that differentiate into spores that allow for survival

Hubert and Mary P. Lechevallier

Figure 16.34 *Nocardia*. A young colony of an actinomycete of the genus *Nocardia*, showing typical filamentous cellular structure (mycelium). Each filament is about 0.8–1 μm in diameter.

and dispersal. We focus here on the genus *Streptomyces*, the most important genus in this group.

Streptomyces

Over 600 species of *Streptomyces* are recognized. *Streptomyces* filaments are typically 0.5–1.0 μm in diameter and of indefinite length, and often lack cross-walls in the vegetative phase. *Streptomyces* grow at the tips of the filaments and may branch often. Thus, the vegetative phase consists of a complex, tightly woven matrix, resulting in a compact, convoluted mycelium and subsequent colony. As the colony ages, characteristic aerial filaments called *sporophores* are formed, which project above the surface of the colony and give rise to spores (Figure 16.35).

Figure 16.36 Spore formation in *Streptomyces*. Diagram of stages in the conversion of an aerial hypha (sporophore) into spores (conidia).

Streptomyces spores, called *conidia*, are quite distinct from the endospores of *Bacillus* and *Clostridium*. Unlike the elaborate cellular differentiation that leads to the formation of an endospore, conidia are produced by the formation of cross-walls in the multinucleate sporophores followed by separation of the individual cells directly into spores (Figure 16.36). Differences in the shape and arrangement of aerial filaments and spore-bearing structures

of various species are among the fundamental features used in classifying the *Streptomyces* species (Figure 16.37). The conidia and sporophores are often pigmented and contribute a characteristic color to the mature colony (Figure 16.38). The dusty appearance of the mature colony, its compact nature, and its color make detection of *Streptomyces* colonies on agar plates relatively easy (Figure 16.38b).

Ecology and Isolation of *Streptomyces*

Although a few streptomycetes are aquatic, they are primarily soil organisms. In fact, the characteristic earthy odor of soil is caused by the production by streptomycetes of a series of complex metabolites all called *geosmin*. Alkaline to neutral soils are more favorable for the development of *Streptomyces* than are acid soils. Moreover, higher numbers of *Streptomyces* are found in well-drained soils (such as sandy loams or soils covering limestone), where conditions are more likely to be aerobic, than in waterlogged soils, which quickly become anoxic.

Isolation of *Streptomyces* from soil is relatively easy: A suspension of soil in sterile water is diluted and spread on selective agar medium, and the plates are incubated aerobically at 25°C (Figure 16.38). Media selective for *Streptomyces* contain mineral salts plus polymeric substances such as starch or casein as organic nutrients. Streptomycetes typically produce extracellular hydrolytic enzymes that permit utilization of polysaccharides (starch, cellulose, and hemicellulose), proteins, and fats, and some strains

Figure 16.37 Morphologies of spore-bearing structures in the streptomycetes. A given species of *Streptomyces* produces only one morphological type of spore-bearing structure. The term “verticillate” means “whorls.”

TABLE 16.2 Some common antibiotics synthesized by species of <i>Streptomyces</i> and related <i>Actinobacteria</i>			
Chemical class	Common name	Produced by	Active against ^a
Aminoglycosides	Streptomycin	<i>S. griseus</i> ^b	Most gram-negative <i>Bacteria</i>
	Spectinomycin	<i>Streptomyces</i> spp.	<i>Mycobacterium tuberculosis</i> , penicillinase-producing <i>Neisseria gonorrhoeae</i>
	Neomycin	<i>S. fradiae</i>	Broad spectrum, usually used in topical applications because of toxicity
Tetracyclines	Tetracycline	<i>S. aureofaciens</i>	Broad spectrum, gram-positive and gram-negative <i>Bacteria</i> , rickettsias and chlamydias, <i>Mycoplasma</i>
	Chlortetracycline	<i>S. aureofaciens</i>	As for tetracycline
Macrolides	Erythromycin	<i>Saccharopolyspora erythraea</i>	Most gram-positive <i>Bacteria</i> , frequently used in place of penicillin; <i>Legionella</i>
	Clindamycin	<i>S. lincolnensis</i>	Effective against obligate anaerobes, especially <i>Bacteroides fragilis</i> , the major cause of anaerobic peritoneal infections
Polyenes	Nystatin	<i>S. noursei</i>	Fungi, especially <i>Candida</i> (a yeast) infections
	Amphotericin B	<i>S. nodosus</i>	Fungi
None	Chloramphenicol	<i>S. venezuelae</i>	Broad spectrum; drug of choice for typhoid fever

^aMost antibiotics are effective against several different *Bacteria*. The entries in this column refer to the common clinical application of a given antibiotic. The structures and mode of action of many of these antibiotics are discussed in ► Sections 28.5–28.7.
^bAll species names beginning with an “S.” are species of *Streptomyces*.

can use hydrocarbons, lignin, tannin, and other polymers. After incubation for 5–7 days in air, the plates are examined for the presence of the characteristic *Streptomyces* colonies (Figure 16.38), and spores from colonies can be restreaked to isolate pure cultures.

Antibiotics of *Streptomyces*

Perhaps the most striking physiological property of the streptomycetes is the extent to which they produce *antibiotics* (Table 16.2). Evidence for antibiotic production is often seen on the agar plates used in their initial isolation: Adjacent colonies of other bacteria show zones of inhibition (Figure 16.39a).

About 50% of all *Streptomyces* isolated have been found to be antibiotic producers. Over 500 distinct antibiotics are produced by streptomycetes and many more are suspected; most of these have been identified chemically. Some species produce more than one antibiotic, and often the several antibiotics produced by one organism are chemically unrelated. Although an antibiotic-producing organism is resistant to its own antibiotics, it usually remains sensitive to antibiotics produced by other streptomycetes. Many genes are required to encode the enzymes for antibiotic synthesis, and because of this, the genomes of *Streptomyces* species are typically quite large (8 Mbp and larger; compare with genome sizes in Table 10.1). More than 60 streptomycete antibiotics have been used in human and veterinary medicine, and some of the most commonly used are listed in Table 16.2.

Surprisingly, despite the extensive research done on antibiotic-producing streptomycetes by the antibiotic industry and the fact that *Streptomyces* antibiotics are a multibillion-dollar-a-year industry, the

(a)

(b)

Figure 16.39 Antibiotics from *Streptomyces*. (a) Antibiotic action of soil microorganisms on a crowded agar plate. The smaller colonies surrounded by inhibition zones (arrows) are streptomycetes; the larger, spreading colonies are *Bacillus* species, some of which are also producing antibiotics. (b) The red-colored antibiotic undecylprodigiosin is being excreted by colonies of *S. coelicolor*.

ecology of *Streptomyces* remains poorly understood. The interactions of these organisms with other bacteria and the ecological rationale for antibiotic production remains an important topic about which we know very little. One hypothesis for why *Streptomyces* species produce antibiotics is that antibiotic production, which is linked to sporulation (a process itself triggered by nutrient depletion), might be a mechanism to inhibit the growth of other organisms competing with *Streptomyces* cells for limiting nutrients. This would allow the *Streptomyces* to complete the sporulation process and form a dormant structure that would increase their chances of survival.

Check Your Understanding

- Contrast spores and sporulation in *Streptomyces* and *Bacillus* species.
- Why might antibiotic production be of advantage to streptomycetes?

III • Bacteroidetes

The Bacteroidetes include aerobes such as *Cytophaga*, which are common in natural habitats, and obligate anaerobes such as *Bacteroides*, which are common in the guts of many animals. Many of these species are motile by gliding.

The phylum *Bacteroidetes* contains more than 1000 characterized species spread across four primary orders: *Bacteroidales*, *Cytophagales*, *Flavobacteriales*, and *Sphingobacteriales* (Figure 16.40). The *Bacteroidetes* are gram-negative, nonsporulating rods; species are typically saccharolytic and can be aerobic or fermentative, including obligate aerobes, facultative aerobes, and obligate anaerobes. Gliding motility (◀ Section 2.10) is widespread in the phylum, though many species are nonmotile and a few are motile by flagella. The genus *Bacteroides* has been particularly well studied as these organisms are a major component of the microbial community in the human gut. But as we will see in Chapter 20, as a group, *Bacteroidetes* are found almost everywhere in nature and are diverse and common inhabitants of most terrestrial and aquatic environments.

Figure 16.40 Major orders of Bacteroidetes. The phylogenetic tree was constructed from 16S rRNA gene sequences of representative genera of *Bacteroidetes*. Order names are shown in bold.

Figure 16.41 Sphingolipids. Comparison of (a) glycerol with (b) sphingosine. In sphingolipids, characteristic of *Bacteroides* species, sphingosine is the esterifying alcohol; a fatty acid is bonded by peptide linkage through the N atom (shown in red), and the terminal —OH group (shown in green) can be part of any of a number of compounds including phosphatidylcholine (sphingomyelin) or various sugars (cerebrosides and gangliosides).

16.13 Bacteroidales

KEY GENUS: Bacteroides

The order *Bacteroidales* primarily contains obligately anaerobic fermentative species. The type genus is *Bacteroides*, which contains species that are saccharolytic, fermenting sugars or proteins (depending on the species) to acetate and succinate as major fermentation products. *Bacteroides* are normally commensals, found in the intestinal tract of humans and other animals. In fact, *Bacteroides* species are the numerically dominant bacteria in the human large intestine, where measurements have shown that about 10^{11} prokaryotic cells are present per gram of wet feces (▶ Section 24.2). However, species of *Bacteroides* can occasionally be pathogens and are the most important anaerobic bacteria associated with human infections such as *bacteremia* (bacteria in the blood).

Bacteroides thetaiotaomicron is one of the most prominent species of *Bacteroides* found in the lumen of the large intestine. *B. thetaiotaomicron* specializes in the degradation of complex polysaccharides. A majority of its genome is devoted to making enzymes that degrade polysaccharides. The diversity and number of genes for carbohydrate metabolism found in its genome far exceeds those found in any other bacterial species. *B. thetaiotaomicron* produces many enzymes that are not encoded by the human genome and thus it vastly increases the diversity of plant polymers that can be degraded in the human digestive tract.

Species of *Bacteroides* are unusual in that they are one of the few groups of bacteria to synthesize a special type of lipid called *sphingolipid* (Figure 16.41), a collection of lipids characterized by the long-chain amino alcohol sphingosine in place of glycerol in the lipid backbone. Sphingolipids such as sphingomyelin, cerebrosides, and gangliosides are common in mammalian tissues, especially in the brain and other nervous tissues, but are rare in most bacteria. The production of sphingolipids can be found in a number of other genera in the phylum *Bacteroidetes* including *Flectobacillus*, *Prevotella*, *Porphyromonas*, and *Sphingobacterium*.

Check Your Understanding

- What is the role of *Bacteroides thetaiotaomicron* in the human gut?

16.14 Cytophagales, Flavobacteriales, and Sphingobacteriales

KEY GENERA: *Cytophaga*, *Flavobacterium*, *Flexibacter*

Cytophagales

The order *Cytophagales* (Figure 16.40) contains almost exclusively obligate aerobes, though some species have limited fermentative capabilities. Cells are typically long, slender, gram-negative rods, often containing pointed ends, and move by gliding (Figure 16.42). *Cytophagas* specialize in the degradation of complex polysaccharides. They are widespread in toxic soils and freshwaters, where they probably account for much of the bacterial cellulose digestion. Cellulose decomposers can easily be isolated by placing small crumbs of soil on pieces of cellulose filter paper laid on the surface of mineral salts agar. The bacteria attach to and digest the cellulose fibers, forming spreading colonies (Figure 16.42b).

Cellulose degradation by cytophagas can proceed by two different mechanisms. The typical mechanism is the free cellulase mechanism in which cells secrete extracellular enzymes called *exoenzymes* that degrade insoluble cellulose outside of the cell. A complex mixture of enzymes is secreted including *processive endocellulases*, which cleave *internal* β -1,4 glycosidic bonds, and *processive exocellulases*, which cleave *terminal* β -1,4 glucosidic bonds, releasing cellobiose. These exoenzymes degrade insoluble cellulose into soluble polysaccharides and disaccharides that can be readily assimilated by cells. *Cytophaga hutchinsonii* does not produce processive cellulases, and its degradation of cellulose likely requires physical contact of cellulose fibers with cellulase enzymes located on the outer surface of its cell wall.

The genus *Cytophaga* contains species that can degrade not only cellulose (Figure 16.42c) but also agar (Figure 16.42a) and chitin. In pure culture *Cytophaga* can be grown on agar containing embedded cellulose fibers (Figure 16.42b). The related genus *Sporocytophaga* is similar to *Cytophaga* in morphology and physiology, but the cells form resting spherical structures called *microcysts* (Figure 16.42d), similar to those produced by some fruiting myxobacteria (◀ Section 15.16).

Several species of *Cytophaga* are fish pathogens and can cause serious problems in the cultivated fish industry. Two of the most important diseases are *columnaris disease*, caused by *Cytophaga columnaris*, and *cold-water disease*, caused by *Cytophaga psychrophila*. Both diseases preferentially affect stressed fish, such as those living in waters receiving pollutant discharges or living in high-density confinement situations such as fish hatcheries and aquaculture facilities. Infected fish show tissue destruction, frequently around the gills, probably from proteolytic activities of the *Cytophaga* pathogen.

Flavobacteriales and Sphingobacteriales

Flavobacteriales and *Sphingobacteriales* (Figure 16.40) typically contain aerobic and facultatively aerobic chemoorganotrophs. Like most *Bacteroidetes*, these organisms are gram-negative rods, and are saccharolytic with many species motile by gliding. Species are found widely in soils and in aquatic habitats, where they typically degrade complex polysaccharides.

Flavobacteriales can be particularly abundant in marine waters including aquatic systems in polar environments. *Flavobacterium*

Figure 16.42 *Cytophaga* and *Sporocytophaga*. (a) Streak of an agarolytic marine *Cytophaga* hydrolyzing agar in a Petri dish. (b) Colonies of *Sporocytophaga* growing on cellulose. Note the clearing zones (arrows) where the cellulose has been degraded. (c) Phase-contrast micrograph of cells of *Cytophaga hutchinsonii* grown on cellulose filter paper (cells are about 1.5 μm in diameter). (d) Phase-contrast micrograph of the rod-shaped cells and spherical microcysts of *Sporocytophaga myxococcoides* (cells are about 0.5 μm and microcysts about 1.5 μm in diameter). Although *Sporocytophaga* microcysts are only slightly more heat-tolerant than vegetative cells, they are extremely resistant to desiccation and thus help the organism survive dry periods in soil. The genera *Cytophaga* and *Sporocytophaga* form a major clade within the phylum *Bacteroidetes* (Figure 16.40).

species are primarily found in aquatic habitats, both freshwater and marine, as well as in foods and food-processing plants. Most species are obligate aerobes, though some species are able to reduce nitrate in an anaerobic respiration. Flavobacteria frequently produce yellow pigments and are generally saccharophilic; most can also degrade starch and proteins. Flavobacteria are rarely pathogenic; however, one species, *Flavobacterium meningosepticum*, has been implicated in cases of infant meningitis, and several fish pathogens are also known.

Some *Flavobacteriales* are psychrophilic or psychrotolerant (◀ Section 4.12). These include, in particular, the genera *Polaribacter* and *Psychroflexus*, organisms commonly isolated from cold environments, especially permanently cold environments such as polar waters and sea ice. Many related genera are also capable of good growth below 20°C and can thus be agents of food spoilage. None are pathogenic.

Sphingobacteriales are phenotypically similar to many *Flavobacteriales*. In terms of physiology, species of *Sphingobacteriales* are generally able to degrade a greater breadth of complex polysaccharides than are *Flavobacteriales*, and in this regard they resemble species of *Cytophagales*. The genus *Flexibacter* is typical of many genera of *Sphingobacteriales*. Species of *Flexibacter* differ from those of *Cytophaga* in that they usually require complex media for good growth and are unable to degrade cellulose. Cells of some *Flexibacter* species also undergo changes in cell morphology from long, gliding, threadlike filaments lacking cross-walls to short, nonmotile rods. Many flexibacteria are pigmented due to carotenoids located in their cytoplasmic membrane, or from related pigments called *flexirubins*, located in the cell's outer membrane. *Flexibacter* species are common in soil and freshwaters where they degrade polysaccharides, and none have been identified as pathogens.

IV • *Chlamydiae*, *Planctomycetes*, and *Verrucomicrobia*

***Chlamydiae* and *Planctomycetes* lack the key cell-division protein FtsZ and produce unusual cellular structures. *Chlamydiae* include intracellular parasites while *Planctomycetes* and *Verrucomicrobia* are widespread in soils and aquatic systems.**

The phyla *Chlamydiae*, *Planctomycetes*, and *Verrucomicrobia* share an ancestor and are more closely related to each other than to other bacterial phyla (Figure 16.43). These three groups contain organisms that can be found in a variety of habitats including soils, aquatic systems, and in association with eukaryotic hosts. The *Chlamydiae* and *Planctomycetes* are highly unusual among bacteria in that they lack a gene encoding the protein FtsZ, a key protein in septum

Figure 16.43 Major orders of *Chlamydiae*, *Planctomycetes*, and *Verrucomicrobia*. The phylogenetic tree was constructed from 16S rRNA gene sequences of representative genera of *Chlamydiae*, *Planctomycetes*, and *Verrucomicrobia*. Order names are shown in bold.

formation during cell division (◀ Section 8.3). FtsZ is essential for cell division in most bacteria and hence there is great interest in understanding how *Chlamydiae* and *Planctomycetes* divide without this protein. We first consider the chlamydias, a group of small gram-negative bacteria that cause some serious human and animal diseases.

16.15 *Chlamydiae*

KEY GENERA: *Chlamydia*, *Chlamydophila*, *Parachlamydia*

The phylum *Chlamydiae* contains a single order, the *Chlamydiales*. The entire phylum consists of obligate intracellular parasites of eukaryotes, in particular, humans. The genomes of the chlamydias are highly reduced, being about 1 Mbp in size, and as a result they are among the most biochemically limited of all known *Bacteria*. They are unable to synthesize many of the vitamins and growth factors needed to grow and must acquire these molecules from the cytoplasm of infected host cells.

Besides their lack of the key protein FtsZ (◀ Section 8.3), many chlamydial species lack a cell wall. These organisms apparently minimize their use of peptidoglycan as a means of remaining undetected by the host immune system. Despite the complete absence of a cell wall in many species of the *Chlamydiae* these organisms remain susceptible to beta-lactam antibiotics such as penicillin, a drug that prevents peptidoglycan synthesis. The answer to this conundrum is the fact that although they lack a cell wall, chlamydias still require the formation of a ringlike peptidoglycan structure to facilitate septum formation during cell division. In the absence of this structure, cell division is compromised.

Though the chlamydia that are human pathogens have been characterized in most detail, the phylum contains diverse species that interact with a wide variety of eukaryotic hosts including diverse

(a)

(b)

Figure 16.44 The infection cycle of a chlamydia. (a) Schematic diagram of the cycle: The entire cycle takes about 48 h. (b) Human chlamydial infection. Elementary bodies ($\sim 0.3 \mu\text{m}$ in diameter) are the infectious form and reticulate bodies ($\sim 1 \mu\text{m}$ in diameter) are the multiplying form. An infected fallopian tube cell is bursting, releasing mature elementary bodies.

animals and even many amoebae. Species are typically very small cocci, approximately $0.5 \mu\text{m}$ in diameter, and display a distinctive developmental cycle.

Life Cycle of *Chlamydiae*

Species of *Chlamydiae* demonstrate a unique chlamydial life cycle (Figure 16.44). Two types of cells are seen in the life cycle: (1) a small, dense cell, called an *elementary body*, which is relatively resistant to drying and is the means of dispersal, and (2) a larger, less dense cell, called a *reticulate body*, which divides by binary fission and is the vegetative form.

Elementary bodies are nonmultiplying cells specialized for infectious transmission. By contrast, reticulate bodies are noninfectious forms that function only to multiply inside host cells to form a large inoculum for transmission. Unlike the rickettsias, the chlamydias are not transmitted by arthropods but are primarily airborne invaders of the respiratory system—hence the significance of resistance to drying of the elementary bodies. A dividing reticulate body can be seen in Figure 16.45. After a number of cell divisions, these vegetative cells are converted into elementary bodies that are released when the host cell disintegrates (Figure 16.44b) and can then infect other nearby host cells. Generation times of 2–3 h have been measured for reticulate bodies, considerably faster than times found for the rickettsias (Section 16.1).

Notable Genera of *Chlamydiae*

Chlamydiae are particularly well adapted to invading and colonizing eukaryotic cells, and different species can infect a diverse array of eukaryotic hosts. The species *Parachlamydia acanthamoebae* infects

free-living amoebae, particularly amoebae in the genus *Acanthamoeba*. *Parachlamydia* demonstrates the typical chlamydial life cycle during infection of amoebae (Figure 16.44). Most species of *Chlamydiae* can multiply or survive within free-living amoebae, and these hosts may be important for the survival and dispersal of *Chlamydiae* in nature. A diversity of 16S rRNA gene sequences from *Chlamydiae* can be detected in natural environments, suggesting that these organisms are widespread and that many of their natural hosts have yet to be identified. While free-living amoebae are the natural hosts for *P. acanthamoebae*, this species can also infect humans, although only weakly compared with *Chlamydiae* whose natural hosts are human.

Figure 16.45 *Chlamydiae*. Thin-section electron micrograph of a dividing reticulate body of *Chlamydophila psittaci* within a mouse tissue-culture cell. A single chlamydial cell is about $1 \mu\text{m}$ in diameter.

The best-studied human pathogens are found in the genera *Chlamydia* and *Chlamydophila*. Several species are recognized within these genera: *Chlamydophila psittaci*, the causative agent of the disease psittacosis; *Chlamydia trachomatis*, the causative agent of trachoma and a variety of other human diseases; and *Chlamydophila pneumoniae*, the cause of some respiratory syndromes. Psittacosis is an epidemic disease of birds that is occasionally transmitted to humans and causes pneumonia-like symptoms. Trachoma, a debilitating disease of the eye characterized by vascularization and scarring of the cornea, is the leading cause of blindness in humans. Other strains of *C. trachomatis* infect the genitourinary tract, and chlamydial infections are currently one of the leading sexually transmitted diseases (► Section 31.13).

In sum, the chlamydias appear to have evolved an efficient and effective survival strategy including parasitizing the resources of the host and producing resistant cell forms specialized for transmission.

- How are *Chlamydia* and *Mycoplasma* (Section 16.9) similar? How are they different?
- What is the difference between an elementary body and a reticulate body?

16.16 Planctomycetes

KEY GENERA: *Planctomyces*, *Blastopirellula*, *Gemmata*, *Brocadia*

The phylum *Planctomycetes* contains a diverse set of morphologically unique bacteria found primarily in two orders, *Planctomycetales* and *Brocadiales* (Figure 16.43). *Planctomycetes* are gram-negative bacteria that often have stalks or appendages, and many species form rosettes (clusters of cell typically attached at their poles). *Planctomycetes* are found widely in soils and aquatic environments and they are rarely pathogenic. Despite being observed widely in the environment, their ecology remains poorly defined. *Planctomycetes* are remarkable for having a set of unusual cellular features.

Unlike most *Bacteria*, *Planctomycetes* lack the protein FtsZ (see also *Chlamydia*, Section 16.15), and they divide by budding, much like yeast. Moreover, *Planctomycetes* were long thought to lack peptidoglycan, and transmission electron micrographs (TEM) suggested the presence of a membrane-enclosed nucleus in some species (Figure 16.46). This unique mix of prokaryotic and eukaryotic features has for years given the impression that *Planctomycetes* are a missing link in cellular evolution. However, the mysteries of the missing peptidoglycan and the nature of the “nucleus”—like many other microbial mysteries—were ultimately solved by advances in microbiological techniques.

Compartmentalization in *Planctomycetes*

Cryo-electron tomography (CET) is a microscopic method that generates detailed three-dimensional images with nanometer-scale resolution (◀ Section 1.10). CET scans of *Planctomycetes* revealed that what appeared to be a nuclear membrane in two-dimensional transmission electron micrographs was actually a system of deep invaginations of the cytoplasmic membrane (Figure 16.47). The cytoplasmic membrane of cells of *Planctopirus* is heavily invaginated, and when viewed in

Margaret Lindsay and John Fuerst

Figure 16.46 Membrane invaginations in *Gemmata*. Thin-section electron micrograph of a cell of *Gemmata obscuriglobus* showing the nucleoid surrounded by an invagination of the cell membrane (see Figure 16.47). The deep invagination of the cell membrane, when viewed in a two-dimensional section, gives the appearance of a nuclear membrane. The cell is about 1.5 μm in diameter.

Margarete Schuler and Harald Engelhardt

Figure 16.47 Cryo-electron tomographic reconstruction of *Planctopirus*. *Planctomycetes* have a complex cell structure consisting of a series of deep and complex invaginations of the cellular membrane. Until recently, these unusual membrane structures were interpreted as evidence that *Planctomycetes* could have a membrane-bound nucleus (see Figure 16.46). The image shows the internal structure of a single cell and the outer sections of several nearby cells. The structures are color coded: outer membrane (green), a peptidoglycan-containing cell wall (orange), cytoplasmic membrane (blue), DNA-containing nucleoids (yellow), ribosomes (white) present in the cytoplasm, and crateriform structures (magenta) on the outer membrane. The presence of two nucleoids suggest the central cell is preparing to divide.

three dimensions, these invaginations can be seen to wrap around the DNA-containing nucleoid (Figure 16.47). Two-dimensional slices through this three-dimensional system of membranes gave the false appearance of a nuclear membrane (for example, see Figure 16.46). Furthermore, these images clearly reveal that *Planctomycetes* have a typical gram-negative cell envelope containing peptidoglycan.

While we now know that cells of *Planctomycetes* contain both peptidoglycan and a gram-negative cell envelope, an understanding of the remarkable membrane invaginations that appear in CET scans of cells of *Planctomycetes* remains elusive. In addition, these CET scans reveal unusual crateriform structures studding the surface of their outer membranes. It is possible that these crateriform structures mediate the transport of large molecules into the cell where they are then metabolized in the large periplasmic compartments formed by the membrane invaginations. However, the purpose of these cellular features remains unknown.

Another interesting cellular structure found in the *Planctomycetes* is present in the *Brocadiales* that carry out the anammox process (◀ Section 14.10). Anammox bacteria such as *Brocadia anammoxidans* contain a true organelle called the *anammoxosome* (◀ Figure 14.26). These bacteria catalyze the anaerobic oxidation of ammonia (NH_3) within the anammoxosome structure. The anammoxosome membrane is composed of unique lipids that form a tight seal, protecting cytoplasmic components from toxic intermediates produced during the anaerobic oxidation of ammonia (◀ Section 14.10 and Figure 14.26c). The evolutionary origins of this organelle and many aspects of its function remain unknown.

Planctomyces

Planctomyces is the best-characterized genus in the *Planctomycetes*. In Section 15.18 we considered the stalked proteobacterium *Caulobacter*. *Planctomyces* is also a stalked bacterium (Figure 16.48). However, unlike *Caulobacter*, the stalk of *Planctomyces* consists of protein and does not contain a cell wall or cytoplasm (compare Figure 16.48 with ◀ Figure 15.53). The *Planctomyces* stalk presumably functions in attachment, but it is a much narrower and finer structure than the prosthecal stalk of *Caulobacter*.

Like *Caulobacter* (◀ Figures 8.6, 8.20, and 15.54), *Planctomyces* is a budding bacterium that displays a life cycle. Its motile swarmer

cells attach to a surface, grow a stalk from the attachment point, and generate a new cell from the opposite pole by budding. This daughter cell produces a flagellum, breaks away from the attached mother cell, and begins the cycle anew. Physiologically, *Planctomyces* species are facultatively aerobic chemoorganotrophs, growing either by fermentation or respiration of sugars.

Planctomyces are found primarily in soil and aquatic habitats, both freshwater and marine, and the genus *Isosphaera* is a filamentous, gliding hot spring bacterium. The isolation of *Planctomyces* and relatives, like that of *Caulobacter*, requires dilute media.

Check Your Understanding

- How does the stalk of *Planctomyces* differ from the stalk of *Caulobacter*?
- What is unusual about the bacterium *Planctopirius*?

16.17 Verrucomicrobia

KEY GENERA: Verrucomicrobium, Prostheco bacter

The phylum *Verrucomicrobia* contains at least four orders with characterized species, but most are found within the order *Verrucomicrobiales* (Figure 16.43). Species of *Verrucomicrobia* are aerobic or facultatively aerobic bacteria capable of fermenting sugars. An exception is the genus *Methylacidiphilum*, which contains aerobic methanotrophs (◀ Section 15.15). In addition, some *Verrucomicrobia* form symbiotic associations with protists. *Verrucomicrobia* are widespread in nature, inhabiting freshwater and marine environments as well as forest and agricultural soils. The *Verrucomicrobia* can have membrane-bound intracellular structures similar to those found in the *Planctomycetes*. The *Verrucomicrobia* typically form cytoplasmic appendages called *prosthecae* (◀ Section 15.18). *Verrucomicrobia* share with other prosthecate bacteria the presence of peptidoglycan in their cell walls and in this way are clearly distinct from *Planctomycetes*.

The genera *Verrucomicrobium* and *Prostheco bacter* produce two to several prosthecae per cell (Figure 16.49). Unlike cells of *Caulobacter* (◀ Figures 8.6, 8.20, and 15.54), which contain a single prostheca

Figure 16.48 *Planctomyces maris*. Metal-shadowed transmission electron micrograph. A single cell is about 1–1.5 μm long. Note the fibrillar nature of the stalk. Pili are also abundant. Note also the flagella (curly appendages) on each cell and the bud that is developing from the nonstalked pole of one cell.

Figure 16.49 *Verrucomicrobium spinosum*. Negatively stained transmission electron micrograph. Note the wartlike prosthecae. A cell is about 1 μm in diameter.

and produce flagellated and nonprosthecae swarmer cells, *Verrucomicrobium* and *Prostheco-bacter* divide symmetrically, and both mother and daughter cells contain prosthecae at the time of cell division. The genus name *Verrucomicrobium* derives from Greek roots meaning “warty,” which is an appropriate description of cells of *Verrucomicrobium spinosum* with their multiple projecting prosthecae (Figure 16.49).

Species of the genus *Prostheco-bacter* contain two genes that show significant homology to the genes that encode tubulin in eukaryotic cells. Tubulin is the key protein that makes up the cytoskeleton of eukaryotic cells (◀ Section 2.15). Although the important cell-division protein FtsZ (◀ Section 8.3) is also a tubulin homolog, the *Prostheco-bacter* proteins are structurally more similar to eukaryotic tubulin than is FtsZ. The role of the tubulin proteins in *Prostheco-bacter* is unknown since a eukaryotic-like cytoskeleton has not been observed in these organisms.

Check Your Understanding

- Describe two ways that *Verrucomicrobia* differ from *Planctomycetes*.

V • Hyperthermophilic Bacteria

Aquificales are common in geothermally heated aquatic systems. Hyperthermophilic phyla branch near the root of the bacterial tree, supporting the idea that Earth’s first bacterial cells were thermophilic.

Three phyla of hyperthermophilic bacteria cluster deep in the phylogenetic tree of *Bacteria*, near the root (Figure 16.1). Each group consists of one or two major genera, and a key physiological feature of most species is *hyperthermophily*—optimal growth at temperatures above 80°C (◀ Section 4.13). We begin with *Thermotoga* and *Thermodesulfobacterium*, each representative of its own lineage.

16.18 Thermotogae and Thermodesulfobacteria

KEY GENERA: *Thermotoga*, *Thermodesulfobacterium*

The phylum *Thermotogae* includes about 12 genera containing cultivated organisms. These species are all chemoorganotrophic anaerobes and many are thermophiles and hyperthermophiles, though some mesophiles are known. Species of the representative genus *Thermotoga* are rod-shaped hyperthermophiles that form a sheath-like envelope (called a *toga*; thus the genus name) (Figure 16.50a), stain gram-negatively, and are nonsporulating. *Thermotoga* species are fermentative anaerobes, catabolizing sugars or starch and producing lactate, acetate, CO₂, and H₂ as fermentation products. The organisms can also grow by anaerobic respiration using H₂ as an electron donor and ferric iron as an electron acceptor. Species of *Thermotoga* have been isolated from terrestrial hot springs as well as marine hydrothermal vents.

Despite being bacterial, the genome of *Thermotoga* contains many genes that show strong homology to genes from hyperthermophilic *Archaea*. In fact, over 20% of the genes of *Thermotoga* probably originated from *Archaea* by horizontal gene transfers (◀ Section 13.9 and Chapter 9). Although a few archaeal-like genes have been identified

Figure 16.50 Hyperthermophilic Bacteria. Electron micrographs of two hyperthermophiles: (a) *Thermotoga maritima*—temperature optimum, 80°C. Note the outer covering, the toga. (b) *Aquifex pyrophilus*—temperature optimum, 85°C. Cells of *Thermotoga* measure 0.6 × 3.5 μm; cells of *Aquifex* measure 0.5 × 2.5 μm.

in the genomes of other *Bacteria* and vice versa, only in *Thermotoga* has such large-scale horizontal transfer of genes between domains been detected thus far.

Thermodesulfobacterium (Figure 16.51) is a thermophilic sulfate-reducing bacterium, positioned on the phylogenetic tree in a separate phylum after *Thermotoga* and *Aquifex* (Figure 16.1a). *Thermodesulfobacterium* is a strict anaerobe that uses compounds such as lactate, pyruvate, and ethanol (but not acetate) as electron donors, as do sulfate-reducing bacteria such as *Desulfovibrio* (◀ Section 15.11), reducing SO₄²⁻ to H₂S.

An unusual biochemical feature of *Thermodesulfobacterium* is the production of *ether-linked lipids*. Recall that such lipids are a hallmark of the *Archaea* and that a polyisoprenoid C₂₀ hydrocarbon (phytanyl) replaces fatty acids as the side chains in archaeal lipids (◀ Section 2.1). However, the ether-linked lipids in *Thermodesulfobacterium* are unusual because the glycerol side chains are not

Figure 16.51 Thermodesulfobacterium. (a) Phase-contrast micrograph of cells of *Thermodesulfobacterium thermophilum*. (b) Structure of one of the lipids of *Thermodesulfobacterium mobile*. Note that although the two hydrophobic side chains are ether-linked, they are not phytanyl units, as in *Archaea*. The designation “R” is for a hydrophilic residue, such as a phosphate group.

phytanyl groups, as they are in *Archaea*, but instead are composed of unique C_{17} hydrocarbons along with some fatty acids (Figure 16.51b). Thus we see in *Thermodesulfobacterium* both a deep phylogenetic lineage (Figure 16.1) and a lipid profile that combines features of both the *Archaea* and the *Bacteria*. However, a few other *Bacteria* have also been found to contain ether-linked lipids, and thus these lipids may be more common among *Bacteria* than previously thought.

Check Your Understanding

- What is unique about the genome of *Thermotoga* and the lipids of *Thermodesulfobacterium*?

16.19 Aquificae

KEY GENERA: *Aquifex*, *Thermocrinis*

The genus *Aquifex* (Figure 16.50b) is an obligately chemolithotrophic and autotrophic hyperthermophile and is the most thermophilic of all known *Bacteria*. Various *Aquifex* species utilize H_2 , sulfur (S^0), or thiosulfate ($S_2O_3^{2-}$) as electron donors and O_2 or nitrate (NO_3^-) as electron acceptors, and grow at temperatures up to $95^\circ C$. *Aquifex* can tolerate only very low O_2 concentrations (microaerophilic), and is unable to oxidize any tested organic compound. *Hydrogenobacter*, a relative of *Aquifex*, shows most of the same properties as *Aquifex*, but is an obligate aerobe.

Aquifex and Autotrophy

Autotrophy in *Aquifex* occurs by way of the reverse citric acid cycle, a series of reactions previously detected only in green sulfur bacteria (◀ Sections 14.2 and 15.6) within the domain *Bacteria*. The genome sequence of *Aquifex aeolicus* reveals that an entirely chemolithotrophic and autotrophic lifestyle is encoded by a genome of only 1.55 Mbp (one-third the size of the *Escherichia coli* genome). The discovery that so many hyperthermophilic species of *Archaea* and *Bacteria*, like *Aquifex*, are H_2 chemolithotrophs, coupled with the finding that they branch as very early lineages on their respective phylogenetic trees (Figure 16.1a), suggests that H_2 was a key electron donor for energy metabolism in primitive organisms that appeared on early Earth and also suggests that the earliest cells may have been thermophiles (◀ Section 13.1 and ▶ Section 17.14).

Thermocrinis

Thermocrinis (Figure 16.52) is a relative of *Aquifex* and *Hydrogenobacter*. This bacterium grows optimally at $80^\circ C$ as a chemolithotroph oxidizing H_2 , $S_2O_3^{2-}$, or S^0 as electron donors, with O_2 as electron acceptor. *Thermocrinis ruber*, the only known species, grows in the outflow of certain hot springs in Yellowstone National Park (Figure 16.52a) where it forms pink “streamers” consisting of a filamentous form of the cells attached to siliceous sinter (Figure 16.52b). In static culture, cells of *T. ruber* grow as individual rod-shaped cells (Figure 16.52c). However, when cultured in a flowing system in which growth medium is trickled over a solid glass surface to which cells can attach, *Thermocrinis* assumes the streamer morphology it forms in its constantly flowing habitat in nature.

(a)

(b)

(c)

Figure 16.52 *Thermocrinis*. (a) Octopus Spring, Yellowstone National Park (USA). The source water of this alkaline and siliceous hot spring is $92^\circ C$. (b) Cells of *Thermocrinis ruber* growing as filamentous streamers (arrow) attached to siliceous sinter in the outflow ($85^\circ C$) of Octopus Spring (▶ Figure 17.19b). (c) Scanning electron micrograph of rod-shaped cells of *T. ruber* grown on a silicon-coated cover glass. A single cell of *T. ruber* is about $0.4\ \mu m$ in diameter and from 1 to $3\ \mu m$ long.

T. ruber is of historical significance in microbiology because it was one of the organisms discovered in the 1960s by Thomas Brock, a pioneer in the field of thermal microbiology and senior author of the first seven editions of this text. The discovery by Brock that the pink streamers (Figure 16.52b) contained protein and nucleic acids clearly indicated that they were living organisms and not just mineral debris. Moreover, the presence of streamers in 80 – $90^\circ C$ hot spring outflow waters but not those of lower temperatures supported Brock's hypothesis that these organisms actually *required* heat for growth and were therefore likely to be present in even boiling or superheated waters. Both of these conclusions were subsequently supported by

the discovery by Brock, Karl Stetter of Germany, and many other microbiologists of dozens of genera of hyperthermophilic *Bacteria* and *Archaea* inhabiting hot springs, hydrothermal vents, and other thermal environments. More coverage of hyperthermophiles can be found in Section 4.13 and Chapter 17.

Check Your Understanding

- Of what evolutionary significance is the fact that organisms in the *Aquifex* lineage are both hyperthermophilic and H₂ chemolithotrophs?

VI • Other *Bacteria*

***Bacteria* such as *Acidobacteria* and *Fusobacteria* are difficult to cultivate but are abundant and important components of various natural habitats and the human microbiome, respectively. *Deinococcus* and *Thermus* can survive extremes of radiation and temperature, respectively.**

Thus far in this chapter we have focused on phyla that have many described species (Figure 16.1). Beyond these mainstream bacterial phyla are many others that have but one or at most a handful of characterized species (Figure 16.1*b*). In addition, many more phyla are known only from community sampling of 16S rRNA genes from nature (► Sections 19.6 and 19.8). We cannot cover them all. So in this final part of the chapter we consider two more phyla that have been well studied and then summarize some other phyla that are emerging into the mainstream of microbial diversity.

16.20 *Deinococcus–Thermus*

KEY GENERA: *Deinococcus*, *Thermus*

The *deinococci* group contains only a few characterized genera in two orders, the *Deinococcales* and the *Thermales*. Members of this phylum

are typically aerobic chemoorganotrophs that metabolize sugars, amino and organic acids, or various complex mixtures. Though deinococci stain gram-positively, they have a gram-negative cell wall structure (Figure 16.53) made up of several layers, including an outer membrane, which is characteristic of gram-negative bacteria (◀ Section 2.3). However, unlike the outer membrane of bacteria such as *Escherichia coli*, the outer membrane of deinococci lack lipid A. Deinococci also contain an unusual form of peptidoglycan in which ornithine replaces diaminopimelic acid in the *N*-acetylmuramic acid cross-links (◀ Section 2.3).

Species of *Thermales* are typically thermophiles or hyperthermophiles and the type genus is *Thermus*. *Thermus aquaticus*, discovered in a Yellowstone National Park hot spring in the mid-1960s by Thomas Brock (Section 16.19), has been a model organism for studying life at high temperatures. *T. aquaticus* has subsequently been isolated from many thermal systems including private and commercial hot water heaters and is the source of *Taq* DNA polymerase. Because it is so heat-stable, *Taq* polymerase allowed the polymerase chain reaction (PCR) technique for amplifying DNA to be fully automated (◀ Section 12.1), an advance that revolutionized all of biology.

Radiation Resistance of *Deinococcus radiodurans*

Species of *Deinococcales* have the unusual property of being extremely radiation resistant, and *Deinococcus radiodurans* is the best-studied species in this regard. Most deinococci are red or pink due to carotenoids, and many are highly resistant to both radiation and desiccation. Resistance to ultraviolet (UV) radiation can be used to advantage in isolating deinococci. These remarkable organisms can be selectively isolated from soil, ground meat, dust, and filtered air following exposure of the sample to intense UV (or even gamma) radiation and plating on a rich medium containing tryptone and yeast extract. For example, *D. radiodurans* cells survive exposure to 15,000 grays (Gy) of ionizing radiation (1 Gy = 100 rad). This is

Figure 16.53 The radiation-resistant coccus *Deinococcus radiodurans*. An individual cell is about 2.5 μm in diameter. (a) Transmission electron micrograph of *D. radiodurans*. Note the outer membrane layer. (b) High-magnification micrograph of wall layer. (c) Transmission electron micrograph of cells of *D. radiodurans* colored to show the toroidal morphology of the nucleoid (green).

sufficient to shatter the organism's chromosome into hundreds of fragments (by contrast, some endospores are killed by lower levels, and a human can be killed by exposure to less than 10 Gy) (◀ Section 4.18).

In addition to impressive radiation resistance, *D. radiodurans* is resistant to the effects of many mutagenic agents. The only chemical mutagens that seem to work on *D. radiodurans* are agents such as nitrosoguanidine, which induces deletions in DNA. Deletions are apparently not repaired as efficiently as point mutations in this organism, and mutants of *D. radiodurans* can be isolated in this way.

DNA Repair in *Deinococcus radiodurans*

Studies of *D. radiodurans* have shown that it is highly efficient in repairing damaged DNA. Several different DNA repair enzymes exist in *D. radiodurans*. In addition to the DNA repair enzyme RecA (◀ Sections 9.4 and 9.5), several RecA-independent DNA systems exist in *D. radiodurans* that can repair breaks in single- or double-stranded DNA, and excise and repair misincorporated bases. In fact, repair processes are so effective that the chromosome can even be reassembled from a fragmented state.

It is also thought that the unique arrangement of DNA in *D. radiodurans* cells plays a role in radiation resistance. Cells of *D. radiodurans* always exist as pairs or tetrads (Figure 16.53a). Instead of scattering DNA within the cell as in a typical nucleoid, DNA in *D. radiodurans* is ordered into a toroidal (coiled, or stack of rings) structure (Figure 16.53c). Repair is then facilitated by the fusion of nucleoids from adjacent compartments, because their toroidal structure provides a platform for homologous recombination. From this extensive recombination, a single repaired chromosome emerges, and the cell containing this chromosome can then grow and divide.

- Describe an unusual biological feature of *Deinococcus radiodurans*.

16.21 Acidobacteria and Nitrospirae

Surveys of environmental DNA (▶ Sections 19.6 and 19.8) reveal *Acidobacteria* and *Nitrospirae* to be abundant and widespread in the environment (Figure 16.1b). Despite their abundance, strains of these phyla have proven difficult to cultivate and much of our knowledge about the *Acidobacteria* and *Nitrospirae* comes from metagenomic surveys that detect their genes in natural samples (◀ Section 10.7). We begin with the *Acidobacteria*, which are notable for their diversity and abundance in soils (▶ Section 20.7 and Figure 20.14).

Acidobacteria

KEY GENUS: *Acidobacterium*

Acidobacteria are widespread in the environment as revealed by analyses of 16S rRNA genes (Figure 16.1b). *Acidobacteria* are common in soils, and especially in acid soils (pH < 6.0), where they often comprise a majority of soil microbial communities. *Acidobacteria* also inhabit freshwater, hot spring microbial mats, wastewater treatment reactors, and sewage sludge. Their abundance,

Figure 16.54 Cells of *Acidisarcina polymorpha*. This species of *Acidobacteria* was isolated from acidic Russian soils and degrades both cellulose and chitin, polymers that are common in soil. Cells typically occur in cuboid packets containing to 6–8 cells encapsulated in a shared polysaccharide (see *Sarcina*, Figure 16.21). Both phase-contrast (a) and TEM (b) images are shown. Cells have an irregular shape and are 1.4–4.4 μm long.

widespread distribution, and phylogenetic diversity suggest they play important ecological roles, especially in soil. Unfortunately, while *Acidobacteria* are widespread in the environment, few have been cultivated (Figure 16.1b) and only a handful of genera have been described.

Most described species of *Acidobacteria* are gram-negative, acid-tolerant, aerobic chemoorganotrophs. For example, *Acidobacterium capsulatum* is an acidophile isolated from acid mine drainage. An obligately aerobic encapsulated bacterium, it grows using various sugars and organic acids. *Acidisarcina polymorpha*, which grows in cuboidal packets of 6–8 cells (Figure 16.54), was isolated from an acidic boreal forest soil and is also acid-tolerant. This bacterium is aerobic and able to degrade polymers such as cellulose and chitin, which are common in soils. *Pyrinomonas methylaliphatogenes* is a thermophile isolated from thermally heated soil. This species is also an acidophilic aerobic chemoorganotroph. *P. methylaliphatogenes* is notable, however, because it can generate energy, but not grow, using atmospheric H_2 , typically present in oxic environments in only trace amounts. It is unclear whether this ability is widespread among *Acidobacteria*, but if so, the ability to survive prolonged starvation might explain why *Acidobacteria* are so common in soils.

Acidophilic, aerobic chemoorganotrophs are common among cultivated strains of *Acidobacteria*, but this phylum contains tremendous phylogenetic diversity spanning at least 26 major subgroups. Not all of these subgroups appear to contain acidophilic organisms and not all are aerobic chemoorganotrophs. For example, *Geothrix fermentans* is a strict anaerobe capable of dissimilative iron reduction (◀ Section 15.13) and can also ferment citrate to acetate plus

succinate. *Holophaga foetida* is a strictly anaerobic acetogen (◀ Section 14.14) that grows by degrading methylated aromatic compounds to acetate. Finally, at least one genus, *Chloracidobacterium*, is phototrophic (◀ Section 15.8).

Nitrospirae

KEY GENUS: *Nitrospira*

The phylum *Nitrospirae* is named for the genus *Nitrospira*, a chemolithotroph that oxidizes nitrite to nitrate and grows autotrophically, as do species of the proteobacterium *Nitrobacter* (◀ Section 15.10). *Nitrospira* inhabits many of the same environments as *Nitrobacter*. However, environmental surveys have shown that *Nitrospira* is much more abundant than *Nitrobacter* in nature, and thus most of the nitrite oxidized in nitrogen-rich environments such as wastewater treatment plants and ammonia-rich soils is probably due to *Nitrospira*. Some species of *Nitrospira* found widely in soils have also been observed to contain the complete pathway for nitrification, oxidizing ammonia all the way to nitrate (◀ Sections 14.9, 15.10, and ▶ Section 21.3). Other key *Nitrospirae* include *Leptospirillum*, an aerobic, acidophilic, iron-oxidizing chemolithotroph (◀ Section 15.14) common in acid mine drainage associated with the mining of coal and iron (▶ Section 22.1).

Check Your Understanding

- In what kind of habitat would you expect to find *Acidobacteria* in high abundance? Make a hypothesis as to why *Acidobacteria* are favored in such habitats.
- What different reactions can *Nitrospira* species perform during the process of nitrification?

16.22 Other Notable Phyla of Bacteria

The basic properties of several other phyla of *Bacteria* are discussed briefly below. Although most of these phyla have few cultured representatives (Figure 16.1b), many may well be of considerable importance. If so, future research on their culture and ecological activities will supply the necessary proof. Until then, we paint a picture of these phyla with a broad brush to summarize their major characteristics in a general way.

Fusobacteria

Fusobacteria are gram-negative nonsporulating rods found in sediments and also the gastrointestinal systems and oral cavities of animals. *Fusobacteria* are obligate anaerobes that ferment carbohydrates, peptides, and amino acids. Species of the genus *Fusobacterium* are a common component of the human microbiome (Chapter 24). *Fusobacteria* have adhesions, molecules that allow them to form strong attachments to other cells, both bacterial and animal. These adhesions allow *Fusobacteria* to play an important structural role in the formation of biofilms called dental plaque in the oral cavity (Figure 16.55). *Fusobacteria* are difficult to cultivate and so their role in the human microbiome was not fully appreciated until the development of DNA-based techniques for studying microbial communities (▶ Section 19.8).

While *Fusobacteria* are common in the microbiome of healthy individuals (Chapter 24), they are also implicated in several human diseases and syndromes. In particular, *Fusobacteria* increase in

Jessica Mark-Welch and Gary Borisy

Figure 16.55 Cells of *Fusobacterium* in human dental plaque. The photo is a light micrograph showing a section of human dental plaque stained by fluorescence in situ hybridization (FISH, ▶ Section 19.5). While streptococci (Section 16.6), stained green here, are common in plaque and are the primary cause of dental caries (cavities, ▶ Section 24.3), plaque is a complex biofilm composed of many different species (each in different colors, see Figures 24.10 and 25.8 and the Chapter 19 MicrobiologyNow on page 648). *Fusobacterium*, stained yellow here, are filamentous bacteria with adhesins that allow them to attach to other cells. This trait allows them to colonize cellular surfaces and play a role in structurally supporting these complex biofilms. *Fusobacteria* grow within the biofilm along with other anaerobic filamentous organisms providing an anchor for lactic acid bacteria that grow closer to the biofilm surface.

abundance in individuals suffering from a range of oral diseases. Inflammation of gum tissue and tears in blood vessels allow *Fusobacteria* and other oral bacteria access to the bloodstream. Such bacteria can be found in arterial plaques and may even play a role in heart disease. In addition, *Fusobacteria* in the bloodstream have also been shown to cause adverse pregnancy outcomes. Finally, *Fusobacteria* in the gut have been shown to attach, colonize, and enhance the growth of colorectal cancer cells. In mice with such tumors, treatment with the antibiotic metronidazole both reduced the abundance of *Fusobacteria* in tumors and reduced tumor growth. It would seem that we still have a lot to learn about the *Fusobacteria*.

Fibrobacteres and *Synergistetes*

Fibrobacteres and *Synergistetes* contain relatively few characterized species (Figure 16.1b), but those that have been cultured employ fermentative metabolisms similar to *Fusobacteria*. Species in these groups are often associated with the gastrointestinal tracts of animals.

While 16S ribosomal RNA genes from *Fibrobacteres* can be recovered from a wide range of habitats, the only characterized species have come from either the rumen or gastrointestinal tracts of animals. The genus *Fibrobacter* contains gram-negative fermentative strict anaerobes. However, unlike most *Fusobacteria* and *Synergistetes*, species of *Fibrobacter* are unable to ferment proteins or amino acids and specialize instead in the fermentation of carbohydrates, including cellulose. In the rumen, cellulose is the major source of energy, and in such environments it supports not only cellulolytic bacteria such as *Fibrobacter* but many noncellulolytic anaerobes that use glucose released during cellulose degradation.

Synergistetes are gram-negative nonsporulating rods found in association with animals and in anoxic environments in terrestrial and marine systems. Described species are typically obligate anaerobes that degrade proteins and are capable of fermenting amino acids. In animals they are most often found in the gastrointestinal tract; for example, *Synergistes jonesii* inhabits the rumen (► Section 23.15). In humans, species of *Synergistetes* have been associated with certain soft tissue wounds and abscesses, dental plaque, and periodontal conditions.

Deferribacteres and Chrysiogenetes

The phyla *Deferribacteres* and *Chrysiogenetes* (Figure 16.1) contain anaerobic chemoorganotrophs that display considerable metabolic diversity with respect to the electron acceptors used in anaerobic respirations (Chapter 14 and ◀ Figure 14.1). Most, though not all, species are able to grow through anaerobic respiration of nitrate to nitrite or ammonium. The *Deferribacteres* group is named for the genus *Deferribacter*, a thermophilic dissimilative ferric iron-reducer

(◀ Sections 14.13 and 15.13) that can also reduce nitrate and metal oxides. *Geovibrio* is a related genus that can also grow using elemental sulfur as an electron acceptor (◀ Section 15.11). The bacterium *Chrysiogenes arsenatis* and its relatives are notable for the ability to couple the oxidation of acetate and a few other organic compounds to the reduction of arsenate as a terminal electron acceptor, reducing it to arsenite. In addition to arsenate, many species of *Chrysiogenetes* can reduce selenate, nitrite, nitrate, thiosulfate, and elemental sulfur in anaerobic respirations (◀ Section 14.13).

Check Your Understanding

- How do *Nitrospira* (Section 16.21) and *Deferribacter* differ in terms of lifestyle and metabolism?
- What metabolic characteristics are shared by most *Fusobacteria*, *Fibrobacteres*, and *Synergistetes*, and what disease in humans has been correlated with the presence of *Synergistetes* and *Fusobacteria*?

Go to **Mastering Microbiology** for videos, animations, practice tests, and more.

CHAPTER REVIEW

I • Proteobacteria

- 16.1** The *Alphaproteobacteria* are the second largest class of *Proteobacteria* and metabolically diverse. Key genera are *Rhizobium*, *Rickettsia*, *Rhodobacter*, and *Caulobacter*.

Q Which genera of *Alphaproteobacteria* are known to form nitrogen-fixing nodules in plants?

- 16.2** The *Betaproteobacteria* are the third largest class of *Proteobacteria* and metabolically diverse. Key genera are *Burkholderia*, *Rhodocyclus*, *Neisseria*, and *Nitrosomonas*.

Q Which order of *Betaproteobacteria* does *Nitrosospora* belong to?

- 16.3** The *Gammaproteobacteria* are the largest and most diverse class of *Proteobacteria* and contain many human pathogens. The *Enterobacteriales*, or enteric bacteria, are the most heavily studied of all bacteria. Key genera are *Escherichia* and *Salmonella*.

Q What is the catalase test? What catalase reaction would you expect from an obligate aerobe? What reaction would you expect from an obligate anaerobe?

- 16.4** The *Pseudomonadales* and *Vibrionales* are among the most common *Gammaproteobacteria*. Key genera are *Pseudomonas* and *Vibrio*.

Q Why is *P. aeruginosa* resistant to many widely used antibiotics?

- 16.5** The *Deltaproteobacteria* and *Epsilonproteobacteria* are smaller and less metabolically diverse classes of *Proteobacteria*. Key genera of *Deltaproteobacteria* are *Myxococcus*, *Desulfobivrio*, and *Geobacter*. Key genera of *Epsilonproteobacteria* are *Campylobacter* and *Helicobacter*.

Q Which environments do *Epsilonproteobacteria* typically inhabit? What role do they play in these environments?

II • Firmicutes, Tenericutes, and Actinobacteria

- 16.6** Lactic acid bacteria such as *Lactobacillus* and *Streptococcus* produce lactate as the primary end product of fermentation, and they have many roles in food production and preservation. The *Firmicutes* are one of the two main phyla of gram-positive bacteria.

Q How are lactic acid bacteria different from other anaerobes, and why are they usually restricted to environments which contain sugar?

- 16.7** Many genera of *Firmicutes* in the orders *Bacillales* and *Clostridiales*, including *Staphylococcus*, *Listeria*, and *Sarcina*, are unable to form endospores.

Q What characteristics of *Listeria* make it a frequent cause of foodborne illness?

- 16.8** Production of endospores is a hallmark of the key genera *Bacillus* and *Clostridium* and is only found in the phylum *Firmicutes*.

Q What is a good strategy for isolating spore-forming bacteria from an environmental sample?

- 16.9** The phylum *Tenericutes* contains the mycoplasmas, organisms that lack cell walls and have very small genomes. Many species are pathogenic for humans, other animals, and plants. The key genus is *Mycoplasma*.

Q Provide an explanation for why the absence of a cell wall might be favorable to *Mycoplasma*.

16.10 *Actinobacteria* are the second major phylum of gram-positive bacteria. *Corynebacterium* and *Arthrobacter* are common gram-positive soil bacteria. *Propionibacterium* ferments lactate to propionate and is the key agent responsible for the unique flavor and texture of Swiss cheese.

Q In what sort of environment would you expect to find large numbers of *Actinobacteria*?

16.11 Species of *Actinobacteria* in the genus *Mycobacterium* are mainly harmless soil saprophytes, but *Mycobacterium tuberculosis* causes the disease tuberculosis.

Q How does the cell wall of *Mycobacterium* influence its reaction to the Gram stain and the acid-fast stain?

16.12 The streptomycetes are a large group of filamentous, gram-positive bacteria that form spores at the end of aerial filaments and are found in the phylum *Actinobacteria*. Many clinically useful antibiotics such as tetracycline and neomycin have come from *Streptomyces* species.

Q How are the spores of streptomycetes different from endospores?

III • *Bacteroidetes*

16.13 The phylum *Bacteroidetes* includes gram-negative rods that do not form spores, many of which have gliding motility. Most species in the order *Bacteroidales* are obligate anaerobes that ferment carbohydrates in anoxic environments. The genus *Bacteroides* contains species that are common in the gastrointestinal tract of animals.

Q What species of *Bacteroidetes* is most abundant in the human gastrointestinal tract, and what role does this organism play in the human gut?

16.14 The *Cytophagales* and *Flavobacteriales* are orders in the *Bacteroidetes* that include aerobic bacteria able to degrade complex polysaccharides such as cellulose. These bacteria are important in organic matter decomposition.

Q What is an exoenzyme and why are these types of organisms important in the degradation of cellulose?

IV • *Chlamydiae*, *Planctomycetes*, and *Verrucomicrobia*

16.15 The phylum *Chlamydiae* includes small obligate intracellular parasites that lack FtsZ and are adept at invading eukaryotic cells. Many species cause various diseases in humans and other animals.

Q Describe the infection cycle of *Chlamydia*.

16.16 The *Planctomycetes* are a group of stalked, budding bacteria that lack FtsZ and have extensive invaginations of the cytoplasmic membrane.

Q What is an anammoxosome and where would you expect to find one?

16.17 Species of *Verrucomicrobia* are distinguished by the multiple prosthecae on their cells and their unique phylogeny.

Q *Verruca* is a word of Latin origin that means “wart.” How do you think the *Verrucomicrobia* got their name?

V • Hyperthermophilic *Bacteria*

16.18 *Thermotogae* and *Thermodesulfobacteria* form two deeply branching phyla within the *Bacteria*. These hyperthermophilic bacteria have proven that extensive horizontal gene transfer has occurred from *Archaea* to *Bacteria* (*Thermotoga*) and that ether-linked lipids are not limited to the *Archaea* (*Thermodesulfobacterium*).

Q How are ether-linked lipids in *Thermodesulfobacterium* unusual?

16.19 The *Aquificae* phylum contains a group of hyperthermophilic, H₂-oxidizing bacteria that form the earliest branch on the tree of the domain *Bacteria*.

Q In what environment might you observe *Thermocrinis ruber*, and what role did this organism play in the discovery of hyperthermophiles?

VI • Other *Bacteria*

16.20 *Deinococcus* and *Thermus* are the major genera in a distinct phylum of *Bacteria*. *Thermus* is the source of the key enzyme in automated PCR, whereas *Deinococcus* is the most radiation-resistant bacterium known, exceeding even many endospores in this regard.

Q What are some of the remarkable properties that allow *Deinococcus* to survive exposure to massive doses of radiation?

16.21 *Acidobacteria* are widespread in many environments, especially acidic soils. While aerobic, acidophilic, chemoorganotrophs are common, the phylum is metabolically and phylogenetically diverse. The genus *Nitrospira* includes ammonia and nitrite-oxidizing bacteria.

Q List four ways in which different species of *Acidobacteria* have been shown to generate energy.

16.22 Species of *Deferribacteres* and *Chrysiogenetes* specialize in various forms of anaerobic respiration. Species of *Synergistetes*, *Fusobacteria*, and *Fibrobacteres* are fermentative anaerobes that inhabit the gastrointestinal tract and other anoxic sites in animals.

Q How is it that *Fusobacteria* from the oral cavity are able to colonize arterial plaque in individuals with heart disease?

APPLICATION QUESTIONS

1. Enteric bacteria, lactic acid bacteria, and propionic acid bacteria have distinctive metabolic traits that can be used to characterize and identify these organisms. Describe the metabolic characteristics of these organisms, name a genus that belongs to each group, and indicate in what way these organisms can be differentiated.
2. Microorganisms have a variety of relationships with oxygen. Describe the terms used to characterize a cell's response to oxygen and give an example from this chapter of an organism that can be described by each of these terms.

CHAPTER GLOSSARY

Acid-fastness a property of *Mycobacterium* species in which cells stained with the dye basic fuchsin resist decolorization with acidic alcohol

Actinomycetes a term used to refer to aerobic filamentous bacteria in the phylum *Actinobacteria*

Coryneform bacteria gram-positive, aerobic, nonmotile, rod-shaped organisms with the characteristic of forming irregular-shaped, club-shaped, or V-shaped cell arrangements, typical of several genera of unicellular *Actinobacteria*

Enteric bacteria a large group of gram-negative, rod-shaped *Bacteria* characterized by a facultatively aerobic metabolism and

commonly found in the intestines of animals

Heterofermentative in reference to lactic acid bacteria, capable of making a mixture of fermentation products typically including lactate, ethanol and CO₂

High G + C gram-positive bacteria a term that refers to bacteria in the *Actinobacteria*

Homofermentative in reference to lactic acid bacteria, producing only lactic acid as a fermentation product

Lactic acid bacteria fermentative bacteria that produce lactic acid, are found in the *Firmicutes*, and are important in the production and preservation of many foods

Low G + C gram-positive bacteria a term that refers to bacteria in the *Firmicutes*

Oligotrophic a term that refers to organisms that grow best under low-nutrient conditions

Propionic acid bacteria gram-positive fermentative bacteria that generate propionate as a fermentation end product and are important in the production of cheese

Proteobacteria the largest and most metabolically diverse phylum of bacteria

Pseudomonad a term used to refer to any gram-negative, polarly flagellated, aerobic rod able to use a diverse suite of carbon sources

17 Diversity of Archaea

MICROBIOLOGYNOW

Methanogens and Global Climate Change

A diversity of methanogens exists within the domain *Archaea*. Methanogens are among the oldest microbes on Earth and have a tremendous impact on our biosphere. Methanogens in nature promote the anaerobic decomposition of organic matter by consuming the products of fermentative and syntrophic metabolisms. Methanogens release methane as a waste product, and this methanogenesis is a natural part of Earth's carbon cycle. However, atmospheric methane has been increasing dramatically since the dawn of the industrial age. Methane, like CO₂, traps heat in the atmosphere, contributing to the greenhouse effect. However, molecule for molecule, methane traps far more heat than does CO₂. Moreover, whereas the increase in atmospheric CO₂ comes mostly from burning fossil fuels, the increase in atmospheric methane comes mostly from human activities that promote methanogenesis.

Human activities have created many new opportunities for methanogens. In particular, domesticated ruminants such as cows, sheep, and goats harbor methanogens within their rumens. In addition, during rice production, farmers flood the soil, generating artificial wetlands that release huge amounts

of methane. These two agricultural activities alone account for a major fraction of global methane emissions. Remarkably, however, human activities have even created new habitats for methanogens under glaciers. The meltwater from this Greenland glacier (photo) is supersaturated with methane and contains DNA from cells of the *Methanomicrobiales*, *Methanosarcinales*, and *Methanobacteriales*, highly diverse groups of methanogens. As climate change accelerates glacier melting, the meltwater makes available ancient organic carbon buried beneath the ice. This meltwater creates large subglacial wetlands that are rapidly colonized by cold-active methanogens.

Massive amounts of organic carbon have been locked away for eons in frozen Arctic soils. As temperatures on Earth increase, this carbon thaws, creating new habitats for methanogens. Thus, accurately predicting the consequences of global climate change will require us to understand methanogen diversity and how humans affect it.

The domain *Archaea* is named for the Archaean eon, the period of geological history when life first spread across Earth (◀ Figure 13.1). In the Archaean, high temperatures and an atmosphere devoid of O₂ and thick in toxic gases enveloped Earth. *Archaea* were once thought to be remnants of this forgotten age since many *Archaea* live in extreme environments such as volcanic systems or salt ponds. We now know, however, that *Archaea* occupy a wide range of habitats and they perform important biogeochemical reactions in soil, the oceans, wetlands, and even in the guts of animals. While *Archaea* and *Bacteria* are both single-celled organisms with prokaryotic cell structure (Chapter 2), these domains are highly differentiated both genetically and physiologically. In many ways, *Archaea* share more features with *Eukarya* than with *Bacteria*. Indeed, it is likely that archaeal cells contributed fundamentally to the origin of the domain *Eukarya* (◀ Section 13.4 and Figure 13.10). In this chapter, we will learn about the enormous phylogenetic and physiological diversity found within the domain *Archaea*.

The *Archaea* are nearly as diverse as the *Bacteria*, but the vast majority of *Archaea* have thus far proven difficult to grow in culture. Hence, it is likely that we still have much to learn about the breadth of characteristics in organisms in this domain. To date, most well-characterized species of *Archaea* come from only two phyla: the *Euryarchaeota* and the *Crenarchaeota* (Figure 17.1). In addition, several species have been isolated from the phylum *Thaumarchaeota*. By contrast, the phyla *Korarchaeota* and *Nanoarchaeota* are represented only by strains grown in coculture or studied using enrichment techniques (▶ Section 19.1). The use of metagenomics (◀ Section 10.7) and single-cell genome sequencing (◀ Section 10.11) has led to an explosion in our understanding of the phylogenetic and physiological diversity of the archaeal domain. As a result, many new phyla of *Archaea* such as

representatives of the DPANN, TACK, and Asgard groups (Figure 17.1) have been discovered relatively recently.

While all *Archaea* share certain features, this domain encompasses considerable physiological diversity. Common traits of all *Archaea* include ether-linked lipids, a lack of peptidoglycan in cell walls (Chapter 2), and structurally complex RNA polymerases that resemble those of *Eukarya* (◀ Section 6.6). These features were likely present in the last common ancestor of the *Archaea*. Genomic analyses suggest that the earliest *Archaea* lived at high temperature, oxidized H₂ as an energy source, and fixed CO₂ using the reductive acetyl-CoA pathway (◀ Section 14.14 and Figure 14.34). Despite their shared phylogenetic origin, contemporary species of *Archaea* are metabolically diverse. *Archaea* can be chemoorganotrophs or chemolithotrophs, they can be respiratory or fermentative, and they can be aerobic or anaerobic using a wide diversity of electron donors and acceptors (Chapter 14).

In addition, certain physiological capabilities are uniquely found within the domain *Archaea*. Methane production, for example, is a unique characteristic of *Archaea* called **methanogens** (◀ Section 14.15, Figures 14.38 and 14.39). Methanogenesis evolved very early within the archaeal domain, and all well-characterized methanogens belong to the phylum *Euryarchaeota*. Methanogenesis is a globally important process that has produced virtually all of the natural gas on Earth and has a significant effect on climate because methane is a strong “greenhouse gas” (▶ Sections 21.1, 21.2; and see page 592). *Archaea* are also well known for containing many examples of **extremophiles** (◀ Section 1.5 and Table 1.2) including **hyperthermophiles** (organisms with growth temperature optima above 80°C), as well as halophiles, acidophiles, and psychrophiles (Chapter 4).

With this brief background and the phylogeny of *Archaea* firmly in mind (Figure 17.1), we now consider the organismal diversity of this fascinating domain of life.

Nanoarchaeota Euryarchaeota Thaumarchaeota Crenarchaeota Korarchaeota

Figure 17.1 Schematic representation of the phylogeny of the major taxonomic orders within the domain *Archaea*. Five major archaeal phyla (studied in pure or highly enriched cultures) and their most representative orders are indicated in color, while other archaeal taxa are indicated in black. While archaeal phyla are nearly as numerous as *Bacteria*, far fewer *Archaea* have been cultivated. Archaeal phyla can be organized into four major branches, or superphyla, consisting of the *Euryarchaeota*, DPANN (represented here by *Nanoarchaeota*, see Section 17.6), TACK (composed of *Thaumarchaeota*, *Aigarchaeota*, *Crenarchaeota*, *Korarchaeota*, and related lineages, see Section 17.8), and Asgard *Archaea* (see Section 17.8). The root of the archaeal tree lies between these four branches though the exact position remains uncertain.

I • Euryarchaeota

The phylum *Euryarchaeota* contains most cultured species of *Archaea*. The group is metabolically diverse and includes methanogens, halophiles, thermophiles, and hyperthermophiles.

Euryarchaeota comprise a large and physiologically diverse group of *Archaea*. This phylum includes methanogens as well as many genera of extremely halophilic (salt-loving) *Archaea*. As a study in physiological contrasts, these two groups are remarkable: Methanogens are the strictest of anaerobes while extreme halophiles are primarily obligate aerobes. Other groups of *Euryarchaeota* include the hyperthermophiles *Thermococcus* and *Pyrococcus*, the hyperthermophilic methanogen *Methanopyrus*, and the cell wall-less *Thermoplasma*, an organism phenotypically similar to the mycoplasmas (◀ Section 16.9). We begin our review of *Euryarchaeota* by reviewing the extremely halophilic *Archaea*.

17.1 Extremely Halophilic Archaea

KEY GENERA: *Halobacterium*, *Haloferax*, *Natronobacterium*

Extremely halophilic *Archaea*, often given the nickname “haloarchaea,” are a diverse group that inhabits environments high in salt. These include naturally salty environments, such as solar salt evaporation ponds and salt lakes, and artificial saline habitats such as the surfaces of heavily salted foods, for example, certain fish and meats. Such salty habitats are called *hypersaline* (Figure 17.2). The term **extreme halophile** is used to indicate that these organisms not only are halophilic but require a very high level of salt, in some cases at levels near saturation (◀ Section 4.15 and Figure 4.27).

An organism is considered an extreme halophile if it requires 1.5 M (about 9%) or more sodium chloride (NaCl) for growth. Most species of extreme halophiles require 2–4 M NaCl (12–23%) for

Figure 17.2 Hypersaline habitats for halophilic Archaea. Hypersaline habitats are home to the halophilic *Archaea*. These organisms not only tolerate salt but *require* salt, and typically in large amounts. (a) The north arm of Great Salt Lake, Utah, a hypersaline lake in which the ratio of ions is similar to that of seawater, but in which absolute concentrations of ions are

several times that of seawater. The green color is primarily from cells of cyanobacteria and green algae. (b) Aerial view near San Francisco Bay, California, of a series of seawater evaporating ponds where solar salt is prepared. The red-purple color is predominantly due to bacterioruberins and bacteriorhodopsin in cells of haloarchaea. (c) Lake Hamara, Wadi El Natroun, Egypt.

A bloom of pigmented haloalkaliphiles is growing in this pH 10 soda lake. Note the deposits of trona ($\text{NaHCO}_3 \cdot \text{Na}_2\text{CO}_3 \cdot 2 \text{H}_2\text{O}$) around the edge of the lake. (d) Scanning electron micrograph of halophilic bacteria including square *Archaea* present in a saltern in Spain.

optimal growth and can grow at salinities as high as 5.5 M NaCl (32%, the limit of saturation for NaCl), although some species grow very slowly at this salinity. Some phylogenetic relatives of extremely halophilic *Archaea*, for example species of *Haloferax* and *Natronobacterium*, are able to grow at much lower salinities, such as at or near that of seawater (about 2.5% NaCl).

Hypersaline Environments: Chemistry and Productivity

Hypersaline habitats are common throughout the world, but extremely hypersaline habitats are rare. Most such environments are in hot, dry areas of the world. Salt lakes can vary considerably in ionic composition. The predominant ions in a hypersaline lake depend on the surrounding topography, geology, and general climatic conditions. Great Salt Lake in Utah (USA) (Figure 17.2a), for example, is essentially concentrated seawater. In this hypersaline lake the relative proportions of the various ions [e.g., sodium (Na^+), chloride (Cl^-), and sulfate (SO_4^{2-})] are those of seawater, although the overall concentration of ions is much higher. In addition, the pH of this hypersaline lake is slightly alkaline.

Soda lakes, in contrast, are highly alkaline hypersaline environments. The water chemistry of soda lakes resembles that of hypersaline lakes such as Great Salt Lake, but because high levels of carbonate minerals are also present in the surrounding strata, the pH of soda lakes is quite high. Waters of pH 10–12 are not uncommon in these environments (Figure 17.2c). In addition, the divalent cations Ca^{2+} and Mg^{2+} are present in only trace amounts in soda lakes because they precipitate out as carbonate salts at high pH and carbonate concentrations.

The diverse chemistries of hypersaline habitats have selected for a large diversity of halophilic microorganisms. Some organisms are unique to one environment while others are widespread. Moreover, despite their extreme conditions, salt lakes can be highly productive ecosystems (the word *productive* here means high levels of autotrophic CO_2 fixation). *Archaea* are not the only microorganisms present. The eukaryotic alga *Dunaliella* (► Figure 18.34a) is the major, if not the sole, oxygenic phototroph in most salt lakes. In highly alkaline soda lakes where *Dunaliella* is absent, anoxygenic phototrophic purple bacteria of the genera *Ectothiorhodospira* and *Halorhodospira* (◄ Section 15.4) predominate. Organic matter originating from primary production by oxygenic or anoxygenic phototrophs sets the stage for growth of haloarchaea, which are chemoorganotrophic organisms. In addition, a few extremely halophilic chemoorganotrophic *Bacteria*, such as *Halanaerobium*, *Halobacteroides*, and *Salinibacter*, thrive in such environments.

Marine salterns are also habitats for extreme halophiles. Marine salterns are enclosed basins filled with seawater left to evaporate, eventually yielding solar sea salt (Figure 17.2b, d). As salterns approach the minimum salinity limits for haloarchaea, the waters turn a reddish-purple color due to the massive growth—called a *bloom*—of cells (the red coloration apparent in Figure 17.2b and c is due to carotenoids and other pigments to be discussed later). Morphologically unusual *Archaea* are often present in salterns, including species with a square or cup-shaped morphology (Figure 17.2d). Extreme halophiles are also present in highly salted foods, such as certain types of sausages, marine fish, and salted pork.

Taxonomy and Physiology of Extremely Halophilic Archaea

The extremely halophilic *Archaea* are found within the taxonomic orders *Halobacteriales*, *Natrialbales*, and *Haloferacales*, which share a common ancestor within the *Euryarchaeota* (Figure 17.1). These three orders constitute the haloarchaea, but they are also sometimes called “halobacteria” because the genus *Halobacterium* (Figure 17.3), the best-studied representative of the extreme halophiles, was discovered and characterized long before the *Archaea* were recognized as an independent domain. Many genera of *Natrialbales*, including *Natronobacterium*, *Natronomonas*, and their relatives, differ from other extreme halophiles in being extremely alkaliphilic as well as halophilic. As befits the geochemistry of their soda lake habitat (Figure 17.2c), these natronobacteria grow optimally at low Mg^{2+} concentrations and alkaline pH (9–11).

Haloarchaea stain gram-negatively, reproduce by binary fission, and do not form spores. Cells of the various cultured genera are rod-shaped, cocci, or cup-shaped, but even cells that form squares are known (Figure 17.2d). Cells of *Haloquadratum* are square and only about 0.1 μm thick. *Haloquadratum* also forms gas vesicles (◄ Section 2.7) that allow cells of this organism to float in its hypersaline habitat, probably as a means to be in contact with air since most extreme halophiles are obligate aerobes. Many other extremely halophilic *Archaea* also produce gas vesicles. A few strains of extreme halophiles are weakly motile by *archaella*, the archaeal analog of bacterial flagella, that rotate to propel the cell forward (◄ Section 2.9), but most halophiles lack archaella. The genomes of *Halobacterium* and *Halococcus* are unusual in that large plasmids (◄ Section 6.2) containing up to 30% of the total cellular DNA are present and the G + C base ratio of these plasmids (near 60% G + C) differs significantly from that of chromosomal DNA (66–68% G + C).

Figure 17.3 Electron micrographs of thin sections of the extreme halophile *Halobacterium salinarum*. A cell is about 0.8 μm in diameter. (a) Longitudinal section of a dividing cell showing the nucleoids. (b) High-magnification electron micrograph showing the glycoprotein subunit structure of the cell wall. Archaeal cell walls are discussed in Section 2.5.

Plasmids from extreme halophiles are among the largest naturally occurring plasmids known.

Most haloarchaea use amino acids or organic acids as electron donors aerobically and require a number of growth factors such as vitamins for optimal growth. A few haloarchaea oxidize carbohydrates aerobically, but this capacity is rare; sugar fermentation does not occur. Electron transport chains containing cytochromes of the *a*, *b*, and *c* types are present in *Halobacterium*, and energy is conserved via a proton motive force arising from electron transport (◀ Sections 3.8 and 3.9). Some haloarchaea can grow anaerobically, as growth by anaerobic respiration linked to the reduction of nitrate or fumarate (◀ Sections 3.10, 14.11, and 14.13) has been demonstrated in certain species.

Water Balance in Extreme Halophiles

Extremely halophilic *Archaea* require large amounts of NaCl for growth. Detailed salinity studies of *Halobacterium* have shown that the requirement for Na⁺ cannot be satisfied by any other ion, even the chemically related ion potassium (K⁺). However, cells of *Halobacterium* need both Na⁺ and K⁺ for growth because each plays an important role in maintaining osmotic balance.

As we learned in Section 4.15, microbes must withstand the osmotic forces they face in their habitats. To do so in a high-solute environment such as the salt-rich habitats of *Halobacterium*, organisms must either accumulate or synthesize solutes intracellularly. These solutes are called **compatible solutes** (◀ Table 4.6). These compounds counteract the tendency of the cell to become dehydrated under conditions of high osmotic strength by placing the cell in positive water balance with its surroundings. Cells of *Halobacterium*, however, do not synthesize or accumulate organic compounds but instead pump large amounts of K⁺ from the environment into the cytoplasm. This ensures that the concentration of K⁺ *inside* the cell is even greater than the concentration of Na⁺ *outside* the cell (Table 17.1). This ionic condition maintains positive water balance.

The *Halobacterium* cell wall (Figure 17.3b) is composed of glycoprotein and is stabilized by Na⁺. Sodium ions bind to the outer surface of the *Halobacterium* wall and are absolutely essential for maintaining cellular integrity. When insufficient Na⁺ is present, the cell wall breaks apart and the cell lyses. This is a consequence of the exceptionally high content of the *acidic* (negatively charged) amino acids aspartate and glutamate in the glycoprotein of the *Halobacterium* cell wall. The negative charge on the carboxyl group of these amino acids is bound to Na⁺; when Na⁺ is diluted away, the negatively charged parts of the proteins tend to repel each other, leading to cell lysis.

Halophilic Cytoplasmic Components

Like cell wall proteins, cytoplasmic enzymes of *Halobacterium* are highly acidic, but it is K⁺, not Na⁺, that is required for activity. This makes sense because K⁺ is the predominant cation in the cytoplasm of cells of *Halobacterium* (Table 17.1). Besides having a highly acidic amino acid composition, halobacterial cytoplasmic proteins typically contain lower levels of hydrophobic amino acids and lysine, a positively charged (basic) amino acid, than do proteins of nonhalophiles. This is also to be expected because in a highly ionic cytoplasm, more polar proteins would tend to remain in solution whereas less polar proteins would tend to cluster and perhaps lose activity. The ribosomes of *Halobacterium* also require high K⁺ levels for stability, whereas ribosomes of nonhalophiles have no K⁺ requirement.

Extremely halophilic *Archaea* are thus well adapted to life in a highly ionic environment. Cellular components exposed to the external environment require high Na⁺ levels for stability, whereas cytoplasmic components require high K⁺ levels. With the exception of a few extremely halophilic species of *Bacteria* that also use K⁺ as a compatible solute, in no other group of prokaryotic cells do we find this unique requirement for such high amounts of specific cations.

Bacteriorhodopsin and Light-Mediated ATP Synthesis in Haloarchaea

Certain species of haloarchaea can catalyze a light-driven synthesis of ATP. This form of phototrophy is not linked to CO₂ fixation, and does not require chlorophyll pigments, and so it is not photosynthesis in the traditional sense. However, other light-sensitive pigments are present, including red and orange carotenoids—primarily C₅₀ pigments called *bacterioruberins*—and inducible pigments involved in energy conservation; we discuss these pigments here.

Under conditions of low aeration, *Halobacterium salinarum* and some other haloarchaea synthesize a protein called **bacteriorhodopsin** and insert it into their cytoplasmic membranes. Bacteriorhodopsin is so named because of its structural and functional similarity to rhodopsin, the visual pigment of the eye. Conjugated to bacteriorhodopsin is a molecule of retinal, a carotenoid-like molecule that can absorb light energy and pump a proton across the cytoplasmic membrane. The retinal gives bacteriorhodopsin a purple hue. Thus cells of *Halobacterium* that are switched from growth under high-aeration conditions to O₂-limiting growth conditions (a trigger of bacteriorhodopsin synthesis) gradually change color from orange-red to purple-red (Figure 17.2) as they synthesize bacteriorhodopsin and insert it into their cytoplasmic membranes.

Bacteriorhodopsin absorbs green light around 570 nm. Following absorption, the retinal of bacteriorhodopsin, which normally exists in a *trans* configuration (Ret_T), becomes excited and converts to the *cis* (Ret_C) form (Figure 17.4). This transformation is coupled to the translocation of a proton across the cytoplasmic membrane. The retinal molecule then decays to the *trans* isomer along with the uptake of a proton from the cytoplasm, and this completes the cycle and resets the proton pump to repeat the process (Figure 17.4). As protons accumulate on the outer surface of the membrane, a proton motive force is generated that is coupled to ATP synthesis through the activity of a proton-translocating ATPase (Figure 17.4; ◀ Section 3.9).

Figure 17.4 Model for the mechanism of bacteriorhodopsin. Light of 570 nm ($h\nu_{570\text{nm}}$) converts the protonated retinal of bacteriorhodopsin from the *trans* form (Ret_T) to the *cis* form (Ret_C), along with translocation of a proton to the outer surface of the cytoplasmic membrane, thus establishing a proton motive force. ATPase activity is driven by the proton motive force.

Bacteriorhodopsin-mediated ATP production in *H. salinarum* supports slow growth of this organism under anoxic conditions. The light-stimulated proton pump of *H. salinarum* also functions to pump Na^+ out of the cell by activity of a Na^+-H^+ antiport system and to drive the uptake of nutrients, including the K^+ needed for osmotic balance. Amino acid uptake by *H. salinarum* is indirectly driven by light as well, because amino acids are cotransported into the cell with Na^+ by an amino acid- Na^+ symporter (◀ Section 2.2); removal of Na^+ from the cell occurs by way of the light-driven Na^+-H^+ antiporter.

Other Rhodopsins

Besides bacteriorhodopsin, at least three other rhodopsins are present in the cytoplasmic membrane of cells of *H. salinarum*. **Halorhodopsin** is a light-driven chloride (Cl^-) pump that brings Cl^- into the cell as the anion for K^+ . The retinal of halorhodopsin binds Cl^- and transports it into the cell. Two other light sensors, called *sensory rhodopsins*, are present in *H. salinarum*. These light sensors control phototaxis (movement toward light, ▶ Section 2.12) by the organism. Through the interaction of a cascade of proteins similar to those in chemotaxis (▶ Sections 2.11 and 7.6), sensory rhodopsins affect archaellar rotation, moving cells of *H. salinarum* toward light where bacteriorhodopsin can function to make ATP (Figure 17.4).

We will learn when we consider marine microbiology (▶ Sections 20.11 and 20.12) that diverse species of chemoorganotrophic *Bacteria* that inhabit the upper layers of the ocean contain bacteriorhodopsin-like proteins called *proteorhodopsins*. As far as is known, proteorhodopsin functions like bacteriorhodopsin except that different spectral forms exist, each form being tuned to the absorption of its own specific wavelength of light. Although the energy generated from proteorhodopsin alone is insufficient to sustain growth, these marine bacteria use proteorhodopsin as a supplement to the ATP they generate from respiration. Proteorhodopsin as a mechanism for energy conservation in marine bacteria makes good ecological

sense because levels of dissolved organic matter in the open oceans are typically very low, and thus a strictly chemoorganotrophic lifestyle would be difficult.

- What benefit does bacteriorhodopsin confer on *Halobacterium salinarum*?

17.2 Methanogenic Archaea

KEY GENERA: *Methanobacterium*, *Methanocaldococcus*, *Methanosarcina*, *Methanopyrus*

Many *Euryarchaeota* are methanogens, microorganisms that produce methane (CH_4) as an integral part of their energy metabolism (methane production is called *methanogenesis*). In Section 14.15 we considered the unique biochemistry of methanogenesis. Later, we will learn how methanogenesis is a major component of the global carbon cycle, serving as the terminal step in the biodegradation of organic matter in many anoxic habitats (▶ Sections 21.1, 21.2, and 21.9). Methanogens are important in a wide range of anoxic habitats including freshwater sediments, wetlands, rice paddies, wastewater treatment plants, geothermal systems, the subsurface of the Earth's crust, and within the guts of many animals.

Diversity and Physiology of Methanogens

Methanogens, often called by their nickname “methanoarchaea,” occur in at least eight taxonomic orders, including *Methanobacteriales*, *Methanococcales*, *Methanopyrales*, *Methanomassiliicoccales*, *Methanomicrobiales*, *Methanocellales*, *Methanosarcinales*, and *Methanonatronarchaeales* (Figure 17.1). Methanogens exhibit considerable morphological and physiological diversity (Figure 17.5 and see Table 17.2). As can be seen in Figure 17.1, methanogens are widespread within the *Euryarchaeota* and do not represent a single coherent phylogenetic group. We have already been introduced to the factors that cause inconsistency between phylogenetic diversity and functional diversity (▶ Section 15.1). In the case of methanogenesis it is most likely that the ability to reduce CO_2 to CH_4 evolved only once within the *Euryarchaeota*, and that gene loss caused lineages such as the haloarchaea and *Thermoplasmatales* to lose the capacity to produce methane. We will also see that *Archaeoglobus* (Section 17.4) still retains some of the genes encoding methanogenesis and can actually produce methane under certain growth conditions.

Methanogens have diverse physiological characteristics, but they are united by their ability to produce methane and by their intolerance to O_2 . Several cofactors required by methanogenic pathways are inhibited by O_2 , and hence all methanogens are obligate anaerobes. As a result, strict anoxic techniques are necessary for their cultivation in isolation. While most methanogens are mesophilic and do not live in extreme environments, a diversity of species have been described including some that grow optimally at very high (see Figure 17.7) or very low temperatures, at very high salt concentrations, or at extremes of pH.

Figure 17.5 Scanning electron micrographs of cells of diverse species of methanogenic *Archaea*. (a) *Methanobrevibacter ruminantium*. A cell is about 0.7 μm in diameter. (b) *Methanobrevibacter arborophilus*. A cell is about 1 μm in diameter. (c) *Methanospirillum hungatei*. A cell is about 0.4 μm in diameter. (d) *Methanosarcina barkeri*. A cell is about 1.7 μm wide.

Methanogens possess a diversity of cell envelope and cell wall configurations. *Methanobacterium* species and relatives (Figure 17.6a) have cell walls composed of *pseudomurein* (Section 2.3). *Methanosarcina* and relatives (Figure 17.6b) have cell walls composed of *methanochondroitin* (so named because of its structural resemblance to chondroitin, the connective tissue polymer of vertebrate animals). In addition, *Methanocaldococcus* (Figure 17.7a) and *Methanoplanus* species have cell walls composed of protein or glycoprotein, respectively. Finally, species such as *Methanospirillum* (Figure 17.5c) use an S-layer (Section 2.5) as their cell wall.

Methanogenic Pathways

Methanogenesis occurs through three different pathways (Table 17.2): CO_2 reduction (Figure 14.38), methylotrophic methanogenesis (Figure 14.39a), and acetoclastic methanogenesis (Figure 14.39b). Each of these pathways relies on *coenzyme M*; methane is ultimately produced by reduction of methyl-CoM to methane (Section 14.15). Through these pathways, methanogens convert a limited number of substrates into methane (Table 17.2). Interestingly, these substrates do not include such common compounds as glucose, organic acids (other than pyruvate), or fatty acids (other than acetate). Methanogens often form syntrophic associations with

fermentative anaerobes (Section 14.22, Section 21.2). In these cooperative systems, the fermentative organisms degrade a wide range of organic molecules into H_2 , CO_2 , and acetate, which are ultimately used as substrates for methanogenesis.

The three methanogenic pathways are distributed across different phylogenetic groups of methanogens (Table 17.3). Methanogenesis by CO_2 reduction occurs widely across the known diversity of methanogens, but not all methanogens can reduce CO_2 . Notably, many species of *Methanosarcinales*, and all species in the *Methanomassiliicoccales*, *Methanonatronarchaeales*, and the genus *Methanospaera* have lost the ability to produce methane by CO_2 reduction (Table 17.3). The CO_2 reduction pathway also allows some methanogens to produce methane from formate or carbon monoxide. In addition, while H_2 is the typical electron donor for methanogenesis by CO_2 reduction, this pathway also allows some methanogens to reduce CO_2 by using electrons from pyruvate or certain alcohols (Tables 17.2 and 17.3).

Acetoclastic methanogenesis is performed by few methanogens and is found exclusively within the *Methanosarcinales* (Table 17.3). Methanogenesis from acetate is a dominant source of methane production in a wide range of environments (Section 21.2). In acetoclastic methanogenesis, electron flow is branched, producing both

A cell is about 1 μm in diameter. (b) *Methanotorris igneus* (temperature optimum, 88°C), thin section. A cell is about 1 μm in diameter. (c) *Methanothermus fervidus* (temperature optimum, 88°C), thin-sectioned electron micrograph. A cell is about 0.4 μm in diameter. (d) *Methanosaeta thermophila* (temperature optimum, 60°C), phase-contrast micrograph. A cell is about 1 μm in diameter. The refractile bodies inside the cells are gas vesicles.

CO₂ and CH₄ as products. Acetoclastic methanogens perform a dismutation of acetate in which the carboxyl group is oxidized to CO₂ while the methyl group is reduced to CH₄ (Table 17.2, ◀ Figure 14.39b). The reductive acetyl-CoA pathway is then used to assimilate carbon into cell biomass.

Methylotrophic methanogenesis can take many forms, but all methylotrophic methanogens use one of two pathways that differ

in important ways. Some methylotrophic methanogens use a branched pathway that produces both CH₄ and CO₂ as products and allows for carbon assimilation from methylated compounds. Other methylotrophic methanogens use a methyl-reducing pathway that produces only CH₄ as a product and does not allow for carbon assimilation from methylated compounds. The branched pathway is found only within the family *Methanosarcinales*. Branched pathways for methylotrophic methanogenesis are similar conceptually to the acetoclastic pathway with a major difference being that methylotrophs do not perform a dismutation, instead oxidizing one molecule to CO₂ so that they can reduce other molecules to CH₄ (Table 17.2). For example, many species of *Methanosarcinales* oxidize one molecule of CH₃OH to CO₂ to generate the six electrons needed to reduce three molecules of CH₃OH to 3 CH₄ and 3 H₂O (◀ Figure 14.39a). In addition, methylotrophic methanogens that use a branched pathway funnel carbon from their oxidative branch into the reductive acetyl-CoA pathway in order to assimilate carbon from methylated compounds.

The methyl-reducing pathway for methylotrophic methanogenesis, in contrast, does not result in the production of CO₂, and methanogens using the methyl-reducing pathway lack the ability to assimilate carbon from methylated compounds. Methylotrophic methanogens such as *Methanospiraeta stadtmanae* are unable to oxidize methyl groups to CO₂ and therefore require an external electron donor—either H₂ or formate—to reduce the methyl group to methane (Tables 17.2 and 17.3). Hence, *M. stadtmanae* produces CH₄ but not CO₂

TABLE 17.2 The three methanogenic pathways and their substrates

I. CO₂ reduction pathway: electrons are typically derived from H₂ Carbon dioxide, CO ₂ Formate, HCOO [−] Carbon monoxide, CO
II. Acetoclastic pathway: electrons are derived from dismutation^a Acetate, CH ₃ COO [−] Pyruvate, CH ₃ COCOO [−]
III. Methylotrophic pathways: electrons are derived either by oxidizing some of the methylated substrate to CO₂ (branched pathway) or by the oxidation of H₂ or formate (methyl-reducing pathway) Methanol, CH ₃ OH Methylamine, CH ₃ NH ₃ ⁺ Dimethylamine, (CH ₃) ₂ NH ₂ ⁺ Trimethylamine, (CH ₃) ₃ NH ⁺ Methyl mercaptan, CH ₃ SH Dimethyl sulfide, (CH ₃) ₂ S

^aIn a dismutation, one part of the molecule is reduced by oxidizing another part of the same molecule.

^aTaxonomic orders are listed in bold. An order is a taxonomic rank that consists of several families; families consist of several genera (◀ Table 13.1).

^bMethanogenic pathways I–III are summarized in Table 17.2.

^cMethylamines can include the substrates methylamine (CH₃NH₂), dimethylamine ((CH₃)₂NH₂), and trimethylamine ((CH₃)₃NH⁺); methyl sulfides can include dimethyl sulfide ((CH₃)₂S) and methyl mercaptan (CH₃SH).

from methylated substrates. In addition, although *M. stadtmanae* and metabolically similar methanogens can make methane from methylated compounds, they are unable to incorporate them as a carbon source. Instead, they typically require an organic carbon source such as acetate, though a few species can also fix CO₂. Besides *M. stadtmanae*, this pattern of methylotrophic methanogenesis is also characteristic of *Methanomicrococcus blatticola* and species in the orders *Methanomassiliicoccales* and *Methanonatronarchaeales* (Table 17.3).

Methanocaldococcus jannaschii as a Model Methanogen

The genomes of the hyperthermophilic methanogen *Methanocaldococcus jannaschii* (Figure 17.7a) and many other methanogens have been sequenced. The 1.66-megabase-pair (Mbp) circular genome of *M. jannaschii*, an organism that has been used as a model for the molecular study of methanogenesis and archaeal motility, contains about 1700 genes, and genes encoding enzymes of methanogenesis and several other key cell functions have been identified. Interestingly, the majority of *M. jannaschii* genes encoding functions such as central metabolic pathways and cell division are similar to those in *Bacteria*. By contrast, most of the *M. jannaschii* genes encoding core molecular processes such as transcription and translation more closely resemble those of eukaryotes. These findings reflect the various traits shared by organisms in the three cellular domains and are consistent with our understanding of how the three domains of cells evolved, as discussed in Chapter 13. However, analyses of the *M. jannaschii* genome also show that fully 40% of its genes have no counterparts in genes from either of the other domains. Some of these are genes that encode the enzymes needed for methanogenesis, of course, but many others likely encode novel cellular functions absent from cells in the other domains or may encode redundant functions carried out by classes of enzymes distinct from those found in *Bacteria* and *Eukarya*.

Methanopyrus, a Hyperthermophilic Methanogen

Methanopyrus (Figure 17.8), the only genus in the order *Methanopyrales*, is a rod-shaped hyperthermophilic methanogen that shares phenotypic properties with both the hyperthermophiles (see Section 17.12) and the methanogens. *Methanopyrus* was isolated from hot sediments near submarine hydrothermal vents and from the walls of “black smoker” hydrothermal vent chimneys (Section 17.11; ▶ Section 20.16 and Figure 20.46). *Methanopyrus* produces CH₄ only from H₂ + CO₂ and grows rapidly for an autotrophic organism

Figure 17.8 *Methanopyrus*. *Methanopyrus* grows optimally at 100°C and can make CH₄ only from CO₂ + H₂. (a) Electron micrograph of a cell of *Methanopyrus kandleri*, the most thermophilic of all known organisms (upper temperature limit, 122°C). This cell measures 0.5 × 8 μm. (b) Structure of the novel lipid of *M. kandleri*. This is the normal glycerol diether of Archaea (◀ Figure 2.3b) except that the side chains are an unsaturated form of phytanyl (called geranylgeraniol) rather than phytanyl.

(generation time <1 h at 100°C). In special pressurized vessels, growth of one strain of *Methanopyrus* has been recorded at 122°C , the highest temperature yet shown to support microbial growth (Sections 17.12 and 17.13).

In addition to its remarkable tolerance to high temperature, *Methanopyrus* is also unusual because it contains membrane lipids found in no other known organism. Recall that in the lipids of Archaea, the glycerol side chains contain **phytanyl** rather than fatty acids bonded in ether linkage to the glycerol (◀ Section 2.1 and Figure 2.3a). In *Methanopyrus*, this ether-linked lipid is an *unsaturated* form of the otherwise saturated biphytanyl tetraethers found in all other hyperthermophilic Archaea (Figure 17.8b). These unusual lipids are thought to help stabilize the cytoplasmic membrane of *Methanopyrus* at its unusually high growth temperatures.

Some *Euryarchaeota* lack cell walls and we consider them next.

- What are the three major pathways of methanogenesis and in what phylogenetic groups are they found?
- What physiological and structural features distinguish the *Methanosarcinales* from other methanogens?

17.3 Thermoplasmatales

KEY GENERA: *Thermoplasma*, *Picrophilus*, *Ferroplasma*

A phylogenetically distinct line of Archaea contains thermophilic and extremely acidophilic genera: *Thermoplasma*, *Ferroplasma*, and *Picrophilus*. These organisms are among the most acidophilic of all known microbes, with *Picrophilus* being capable of growth even below pH 0. Most are thermophilic as well. These genera also form their own taxonomic order within the *Euryarchaeota*, the *Thermoplasmatales* (Figure 17.1). We begin with a description of the mycoplasma-like organisms *Thermoplasma* and *Ferroplasma*.

Archaea Lacking Cell Walls

Thermoplasma and *Ferroplasma* lack cell walls, and in this respect they resemble the mycoplasmas (◀ Section 16.9). *Thermoplasma* (Figure 17.9) is a chemoorganotroph that grows optimally at 55°C and pH 2 in complex media. Two species of *Thermoplasma* have been described, *Thermoplasma acidophilum* and *Thermoplasma volcanium*. Species of *Thermoplasma* are facultative aerobes, growing either aerobically or anaerobically by sulfur respiration (◀ Section 14.12). Most strains of *T. acidophilum* have been obtained from self-heating coal refuse piles. Coal refuse contains coal fragments, pyrite (FeS_2), and other organic materials extracted from coal. When dumped into piles in surface mining operations, coal refuse heats as a result of microbial metabolism bringing it to combustion temperature (Figure 17.10). This sets the stage for growth of *Thermoplasma*, which likely metabolizes organic compounds leached from the hot coal refuse. The second species, *T. volcanium*, has been isolated in hot acidic soils throughout the world and is highly motile by multiple archaella (Figure 17.9b).

To survive the osmotic stresses of life without a cell wall and to withstand the dual environmental extremes of low pH and high temperature, *Thermoplasma* has evolved a unique cytoplasmic membrane structure. The membrane contains a lipopolysaccharide-like

Figure 17.9 *Thermoplasma* species. (a) *Thermoplasma acidophilum*, an acidophilic and thermophilic mycoplasma-like archaeon; electron micrograph of a thin section. The diameter of cells varies from 0.2 to $5\ \mu\text{m}$. The cell shown is about $1\ \mu\text{m}$ in diameter. (b) Shadowed preparation of cells of *Thermoplasma volcanium* isolated from hot springs. Cells are $1\text{--}2\ \mu\text{m}$ in diameter. Notice the abundant archaella (the rotating structures that confer swimming motility on Archaea, ▶ Section 2.9) and irregular cell morphology.

material called *lipoglycan*. This substance consists of glycolipids containing sugars such as mannose and glucose (Figure 17.11), and these glycolipids form a tetraether lipid monolayer membrane. The hydrophobic core of this glycolipid consists of biphytanyl (◀ Section 2.1 and Figure 2.3b). In *Thermoplasma* and similar organisms such as *Sulfolobus*, this basic biphytanyl structure can be modified to include one to four cyclopentane rings, with the number of rings tending to increase in proportion to the temperature of the environment. These glycolipids constitute a major fraction of the total lipids of *Thermoplasma*. The membrane also contains glycoproteins and glycopospholipids, but not sterols. These molecules render the *Thermoplasma* membrane stable to hot, acidic conditions.

Like mycoplasmas (◀ Section 16.9), *Thermoplasma* contains a relatively small genome (1.5 Mbp). In addition, *Thermoplasma* DNA is

Figure 17.10 A typical self-heating coal refuse pile, habitat of *Thermoplasma*. The pile, containing coal debris, pyrite, and other microbial substrates, self-heats as a result of microbial metabolism.

complexed with a highly basic DNA-binding protein that organizes the DNA into globular particles resembling the nucleosomes of eukaryotic cells. This protein is homologous to the histone-like DNA-binding protein HU of *Bacteria*, which plays an important role in organization of the DNA in the cell. In contrast, several other *Euryarchaeota* contain basic proteins homologous to the DNA-binding histone proteins of eukaryotic cells.

Ferroplasma

Ferroplasma is a chemolithotrophic relative of *Thermoplasma*. *Ferroplasma* is a strong acidophile; however, it is not a thermophile, as it grows optimally at 35°C. *Ferroplasma* oxidizes ferrous iron (Fe^{2+}) to ferric iron (Fe^{3+}) to obtain energy and uses CO_2 as its carbon source. The oxidation of Fe^{2+} results in acidification of the environment. *Ferroplasma* grows in mine tailings containing pyrite, which is its energy source. The extraordinary acidophily of *Ferroplasma* allows it to drive the pH of its habitat down to extremely acidic values. After moderate acidity is generated from Fe^{2+} oxidation by acidophilic organisms such as *Acidithiobacillus ferrooxidans* and *Leptospirillum ferrooxidans* (► Sections 21.6, 22.1, and 22.2), *Ferroplasma* becomes active and subsequently generates the very low pH values typical of acid mine drainage. Acidic waters at pH 0 can be generated by the activities of *Ferroplasma*.

Figure 17.11 Structure of a tetraether glycolipid of *Thermoplasma acidophilum*. The dominant glycolipids of *T. acidophilum* have two polar head groups that are connected by ether linkages to a hydrophobic core. This structure causes them to form a thermally stable lipid monolayer (◀ Figure 2.3b). One or both of the polar head groups typically contains a mono- or oligosaccharide that contains glucose (Glu), mannose (Man), and other sugars. The hydrophobic core consists of the straight-chain caldarchaeol (shown), which can be modified to include one to four cyclopentane rings (not shown).

Picrophilus

A phylogenetic relative of *Thermoplasma* and *Ferroplasma* is *Picrophilus*. Although *Thermoplasma* and *Ferroplasma* are extreme acidophiles, *Picrophilus* is even more so, growing optimally at pH 0.7 and capable of growth at pH values lower than 0. *Picrophilus* also has a cell wall (an S-layer; ◀ Section 2.5, Figures 2.14 and 2.36a) and a much lower DNA G + C base ratio than does *Thermoplasma* or *Ferroplasma*. Although phylogenetically related, *Thermoplasma*, *Ferroplasma*, and *Picrophilus* have quite distinct genomes. Two species of *Picrophilus* have been isolated from acidic Japanese solfataras, and like *Thermoplasma*, both grow heterotrophically on complex media.

The physiology of *Picrophilus* is of interest as a model for extreme acid tolerance. Studies of its cytoplasmic membrane point to an unusual arrangement of lipids that forms a highly acid-impermeable membrane at very low pH. By contrast, at moderate acidities such as pH 4, the membranes of cells of *Picrophilus* become leaky and disintegrate. Obviously, this organism has evolved to survive only in highly acidic habitats and shows the most extraordinary acidophily of any known microbe.

Check Your Understanding

- In what ways are *Thermoplasma* and *Picrophilus* similar? In what ways do they differ?
- How does *Thermoplasma* strengthen its cytoplasmic membrane to survive without a cell wall?

17.4 Thermococcales and Archaeoglobales

KEY GENERA: *Thermococcus*, *Pyrococcus*, *Archaeoglobus*, *Ferroplasma*

A few euryarchaeotes thrive in thermal environments and some are hyperthermophiles. We consider here the *Thermococcales* and *Archaeoglobales*, which are two orders of *Euryarchaeota* that contain hyperthermophilic species (Figure 17.1).

Thermococcus and *Pyrococcus*

Thermococcus and *Pyrococcus* are genera within the order *Thermococcales*. *Thermococcus* is a spherical hyperthermophilic euryarchaeote indigenous to anoxic thermal waters in various locations throughout the world. The spherical cells contain a tuft of polar archaella and are thus highly motile (Figure 17.12a). *Thermococcus* is an obligately anaerobic chemoorganotroph that metabolizes proteins and other complex organic mixtures (including some sugars) with elemental sulfur (S^0) as electron acceptor at temperatures from 55 to 95°C.

Pyrococcus (Figure 17.12b) is morphologically similar to *Thermococcus*. *Pyrococcus* differs from *Thermococcus* primarily by its higher temperature requirements; *Pyrococcus* grows between 70 and 106°C with an optimum of 100°C. *Thermococcus* and *Pyrococcus* are also metabolically quite similar. Proteins, starch, or maltose are oxidized as electron donors, and S^0 is the terminal electron acceptor and is reduced to hydrogen sulfide (H_2S). Both *Thermococcus* and *Pyrococcus* form H_2S when S^0 is present, but form H_2 when S^0 is absent (see Table 17.4).

Figure 17.12 Spherical hyperthermophilic Euryarchaeota from submarine volcanic areas. (a) *Thermococcus celer*; electron micrograph of shadowed cells (note tuft of archaella). (b) Dividing cell of *Pyrococcus furiosus*; electron micrograph of thin section. Cells of both organisms are about 0.8 μm in diameter.

Archaeoglobus and Ferroglobus

Archaeoglobus was isolated from hot marine sediments near hydrothermal vents. In its metabolism, *Archaeoglobus* couples the oxidation of H_2 , lactate, pyruvate, glucose, or complex organic compounds to the reduction of SO_4^{2-} to H_2S . Cells of *Archaeoglobus* are irregular cocci (Figure 17.13a) and grow optimally at 83°C.

Archaeoglobus and methanogens share some characteristics. We learned in Section 14.15 about the unique biochemistry of methanogenesis. Briefly, this process requires a series of novel coenzymes, and with rare exceptions, these coenzymes have only been found in methanogens. *Archaeoglobus*, however, also contains many of these coenzymes, and cultures of this organism can actually produce small amounts of CH_4 . In addition, the genome of *Archaeoglobus*, which contains about 2400 genes, shares many genes in common with methanogens (Section 17.2). It seems likely that the ancestor of

Archaeoglobus was a methanogen that lost many of the genes required for methanogenesis. Furthermore, genome analysis suggests that the ancestor of *Archaeoglobus* acquired genes for sulfate reduction as a result of horizontal gene transfer from sulfate-reducing bacteria within the *Deltaproteobacteria* (◀ Section 15.11).

Ferroglobus (Figure 17.13b) is related to *Archaeoglobus* but is not a sulfate reducer. Instead, *Ferroglobus* is an iron-oxidizing chemolithotroph, conserving energy from the oxidation of Fe^{2+} to Fe^{3+} coupled to the reduction of nitrate (NO_3^-) to nitrite (NO_2^-) (see Table 17.4). *Ferroglobus* grows autotrophically and can also use H_2 or H_2S as electron donor in its energy metabolism. *Ferroglobus* was isolated from a shallow marine hydrothermal vent and grows optimally at 85°C.

Ferroglobus is interesting for several reasons, but especially for its ability to oxidize Fe^{2+} to Fe^{3+} under anoxic conditions. This process might help explain the origin of some Fe^{3+} found in ancient rocks dated to before the predicted appearance of cyanobacteria on Earth (◀ Section 13.2). With organisms like *Ferroglobus*, it would have been possible for Fe^{2+} oxidation to proceed without the need for O_2 as an electron acceptor. The metabolism of *Ferroglobus* thus has implications for dating the origin of cyanobacteria and the subsequent oxygenation of Earth. Certain anoxygenic phototrophic bacteria can also oxidize Fe^{2+} under anoxic conditions (◀ Section 14.8), and so several anaerobic routes to ancient Fe^{3+} are possible. This makes it difficult to estimate when cyanobacteria first appeared on Earth and to what degree nonphototrophic organisms helped trigger the Great Oxidation Event (◀ Figure 13.1).

We move on now to Part II where we survey the most recently recognized groups of Archaea, some of which are thermophiles but many of which inhabit common environments such as soil, lakes, and the oceans.

Check Your Understanding

- How do *Thermococcus* and *Pyrococcus* make ATP?
- Compare the energy-yielding metabolisms of *Archaeoglobus* and *Ferroglobus*.

II • Thaumarchaeota and Cryptic Archaeal Phyla

Many Archaea remain uncultured and are only known from metagenomic analyses of various microbial habitats. Thaumarchaeota, a group of nitrifying Archaea, were first detected in this way, but have now been cultured and found to be the most abundant Archaea in nature.

Our understanding of Archaea has been revolutionized by the development of molecular phylogeny (◀ Sections 1.15 and 13.11) and methods for studying microorganisms without needing to cultivate them in the laboratory (▶ Sections 19.4–19.8). The discovery and characterization of *Thaumarchaeota*, *Nanoarchaeota*, and *Korarchaeota* were all enabled by the use of molecular techniques that target 16S ribosomal RNA genes. From these initial efforts, species representing each of these phyla were subsequently isolated or

Figure 17.13 Archaeoglobales. (a) Transmission electron micrograph of the sulfate-reducing hyperthermophile *Archaeoglobus fulgidus*. The cell measures 0.7 μm in diameter. (b) Freeze-etched electron micrograph of *Ferroglobus placidus*, a ferrous iron-oxidizing, nitrate-reducing hyperthermophile. The cell measures about 0.8 μm in diameter.

at least grown in enrichment cultures. In addition, metagenomic and single-cell genome sequencing techniques (◀ Sections 10.7 and 10.11) have made it possible to obtain genome sequence data from organisms without the need to obtain cultures, and this advance has expanded greatly our knowledge of the archaeal domain. We begin our consideration of these newly discovered phyla with the *Thaumarchaeota*.

17.5 *Thaumarchaeota* and Nitrification in Archaea

KEY GENERA: *Nitrosopumilus*, *Nitrososphaera*

Early surveys of 16S ribosomal RNA genes from open-ocean microbial communities resulted in the shocking conclusion that *Archaea* were abundant and widespread in the oceans. At the time, the archaeal domain was considered to contain only extremophiles and obligate anaerobes, and their presence in O_2 -rich temperate and even polar oceanic environments was a major surprise. Even more remarkable, these novel *Archaea* were also discovered to be widespread in soils worldwide.

Phylogenetic analyses of 16S ribosomal RNA gene sequences initially suggested that this novel group of *Archaea* was a deeply divergent lineage of the *Crenarchaeota*, a major group of hyperthermophilic *Archaea* we will consider in Section 17.9. It was only after genome sequence analysis of the marine nitrifier *Nitrosopumilus maritimus* that it became clear that the *Thaumarchaeota* constitute a unique phylum of *Archaea* (Figure 17.1).

Physiological Characteristics of *Thaumarchaeota*

The physiology of *Thaumarchaeota* remained a mystery until the isolation of *Nitrosopumilus maritimus* (Figure 17.14). *N. maritimus* grows chemolithotrophically by oxidizing ammonia (NH_3) to nitrite (NO_2^-) aerobically, the first step in nitrification (◀ Sections 14.9, 15.10, and ▶ Section 21.3). This organism uses CO_2 as its sole carbon source, as do most nitrifying *Bacteria* (◀ Section 15.10). Prior to the discovery of *Thaumarchaeota*—for over 100 years in fact—microbiologists thought only certain species of *Bacteria* catalyzed ammonia oxidation. However, unlike ammonia-oxidizing *Bacteria* such as *Nitrosomonas*, *N. maritimus* is adapted to life under extreme nutrient limitation, as would befit an organism indigenous to open ocean waters. *N. maritimus* can grow at NH_3 concentrations that are

Figure 17.14 *Nitrosopumilus maritimus*, a nitrifying species of marine *Thaumarchaeota*. This organism can oxidize NH_3 present at the very low amounts typical of marine environments. (a) Phase-contrast photomicrograph. (b) Scanning electron micrograph. A single cell of *N. maritimus* is about $0.2\ \mu m$ in diameter.

Figure 17.15 *Nitrososphaera viennensis*, a nitrifying species of soilborne *Thaumarchaeota*. This organism can oxidize NH_3 and urea across a wide range of concentrations. (a) A Viennese garden soil used to enrich *N. viennensis*. (b) Cells of *N. viennensis* can take on many shapes (a condition called pleomorphism), as shown in this transmission electron micrograph of sectioned cells. A single cell of *N. viennensis* is about $0.5\ \mu m$ in diameter.

a hundred times lower than those required by bacterial nitrifiers, and many archaeal nitrifiers are actually inhibited at the higher NH_3 concentrations required to support growth of nitrifying species of *Bacteria*.

Several species of *Thaumarchaeota* have been isolated and characterized, revealing a number of properties common to this group. Species have been isolated from habitats including the oceans, marine sediments, estuaries, soils, and hot springs. All existing isolates are chemolithotrophic ammonia-oxidizers (◀ Section 14.9), and most species, like *N. maritimus*, are able to grow at very low concentrations of NH_3 . The membranes of all *Thaumarchaeota* also contain a unique lipid called *crenarchaeol* (◀ Figure 2.3b, c), a compound limited to species of this phylum. In addition, autotrophy in *Thaumarchaeota* is supported by the 3-hydroxypropionate/4-hydroxybutyrate cycle, a finding that further distinguishes archaeal nitrifiers from nitrifying *Bacteria* that employ the Calvin cycle for CO_2 fixation (◀ Sections 3.12 and 14.2). The 3-hydroxypropionate/4-hydroxybutyrate cycle also allows for the assimilation of organic carbon, and some archaeal nitrifiers have been shown to assimilate pyruvate during mixotrophic growth. Growth temperatures of *Thaumarchaeota* vary widely, as some species thrive in polar seas while others inhabit hot spring environments up to about $75^\circ C$.

Nitrososphaera viennensis was the first species of *Thaumarchaeota* isolated from soil (Figure 17.15). Cells of *N. viennensis* form irregular coccoids, and the organism is both mesophilic and neutrophilic. *N. viennensis* is a mixotroph (an organism that can fix CO_2 but grows best with an organic carbon source) and it grows as an aerobic chemolithotroph using either ammonia or urea as electron donor. When growing on urea, *N. viennensis* uses the enzyme urease to produce ammonia, which is the ultimate electron donor. Like marine species of *Thaumarchaeota*, *N. viennensis* can grow at low concentrations of NH_3 , but unlike archaeal marine nitrifiers, *N. viennensis* can also tolerate high levels (up to 10 mM) of ammonium at neutral pH. Hence, *N. viennensis* and related archaeal nitrifiers may be active in soils containing high levels of ammonia, and in these

Figure 17.16 Cold-dwelling *Thaumarchaeota*. (a) Photo of the Antarctic Peninsula taken from shipboard. The frigid waters that lie under the surface ice are habitats for cold-dwelling *Thaumarchaeota*. (b) Fluorescence photomicrograph of seawater treated with a fluorescent FISH probe (► Section 19.5) specific for species of *Thaumarchaeota* (green cells). Blue cells are stained with DAPI, a fluorescent DNA stain that stains all cells.

environments, they likely compete directly with bacterial nitrifiers. *N. viennensis* was isolated from a backyard garden soil (Figure 17.15a) by using cultivation-independent molecular analyses to monitor its growth in different culture media and tailor enrichment media to the growth needs of the organism. This discovery reminds us that when we open our eyes to the microbial world, major discoveries are often “just underfoot.”

Environmental Distribution of *Thaumarchaeota*

Thaumarchaeota are ubiquitous in soils and found throughout the marine water column from the equator to the polar seas. *Thaumarchaeota* are one of the most abundant and widespread phyla on Earth, and they are often the dominant archaeal group found in soil and marine systems. Indeed, *Thaumarchaeota* account for approximately 20% of prokaryotic cells in the oceans and 1% of all microbes in soils. With the use of fluorescent phylogenetic probes (FISH, ► Section 19.5), *Thaumarchaeota* have been detected in oxic marine waters worldwide, and they are highly abundant in sea ice near Antarctica (Figure 17.16). Marine species are planktonic (suspended freely or attached to suspended particles in the water column, Figure 17.16b) and present in significant numbers ($\sim 10^4$ /ml) in waters that are both nutrient-poor and very cold (0–4°C in seawater and below 0°C in sea ice). Marine *Thaumarchaeota* are particularly abundant in the deep ocean, where they can also account for up to 40% of picoplankton (► Section 20.12). The NH_3 concentration in marine waters is often near the threshold for archaeal nitrification, suggesting that *Thaumarchaeota* may play a major role in controlling NH_3 levels in the oceans.

Thaumarchaeota are also common in soils, sometimes outnumbering nitrifying *Bacteria* by 1000-fold, and are found across a wide range of soil pH, from about 3 to 9. While widely present in soils, *Thaumarchaeota* may be particularly important in acid soils (pH <5.5), which make up more than 30% of all soils. Nitrifiers oxidize NH_3 , but at low pH, NH_4^+ predominates and is thus unavailable for nitrification. While nitrification occurs in acid soils, and often at high rates, bacterial nitrifiers have not been observed to grow below

pH 6.3. In contrast, the thaumarchaeotal species *Nitrosotalea devanattera*, isolated from acidic agricultural soil, grows optimally at pH 4–5. The ability of *Thaumarchaeota* to grow at low NH_3 concentrations explains how they can be successful in acidic soils where free NH_3 is present in very low concentration.

Check Your Understanding

- How does the organism *Nitrosopumilus maritimus* conserve energy and obtain carbon?
- In what environments might you expect to find species of *Thaumarchaeota*?

17.6 *Nanoarchaeota* and the “Hospitable Fireball”

KEY GENUS: *Nanoarchaeum*

The *Nanoarchaeota* are represented by a single species, the highly unusual *Nanoarchaeum equitans* (Figure 17.17). *N. equitans* is one of the smallest cellular organisms known and has the smallest genome among species of *Archaea* (0.49 Mb). The coccoid cells of *N. equitans* are very small, about 0.4 μm in diameter, and have only about 1% of the volume of an *Escherichia coli* cell. They cannot grow in pure culture and replicate only when attached to the surface of their host organism, *Ignicoccus hospitalis* (Section 17.11), a hyperthermophilic species of *Crenarchaeota* whose name means “the hospitable fireball.” *N. equitans* grows to 10 or more cells per *Ignicoccus* cell and lives an apparently parasitic lifestyle, making it the only known archaeal symbiont. Indeed, in agreement with its lifestyle, the species epithet *equitans* means “riding,” as in “riding the fireball.”

Nanoarchaeum and Its Host

N. equitans and its host *Ignicoccus* were first isolated from a submarine hydrothermal vent (► Section 20.16) off the coast of Iceland. However, environmental sampling of 16S ribosomal RNA genes (► Section 19.6) indicates that organisms phylogenetically similar to *N. equitans* exist in other submarine hydrothermal vents and in terrestrial hot springs, so *Archaea* of this kind are probably distributed worldwide in suitable hot habitats. Like its host *Ignicoccus*, *N. equitans* grows at temperatures from 70 to 98°C and optimally at 90°C.

The metabolism of *Nanoarchaeum* is not fully understood, but it likely depends on its host for many metabolic functions. *Ignicoccus* is an autotroph that uses H_2 as an electron donor and S^0 as an electron acceptor and probably supplies *N. equitans* with organic carbon. From analyses of its genome (see next subsection), *N. equitans* is incapable of metabolizing H_2 and S^0 for energy. Thus, whether it generates ATP from substances obtained from *Ignicoccus* or obtains its ATP directly from its host is unknown. The appearance of *N. equitans* cells is typical of *Archaea*, with a cell wall consisting of an S-layer (◄ Section 2.5) that overlays what appears to be a periplasmic space (Figure 17.17b).

The *Nanoarchaeum equitans* Genome

The sequence of the *N. equitans* genome provides insight into this organism’s obligately parasitic lifestyle. Its single, circular genome is only 490,885 nucleotides long, one of the smallest cellular

Figure 17.17 *Nanoarchaeum equitans*. (a) Fluorescence micrograph of cells of *N. equitans* (red) attached to cells of *Ignicoccus* (green). Cells were stained by FISH (▶ Section 19.5) using specific nucleic acid probes targeted to each organism. (b) Transmission electron micrograph of a thin section of a cell of *N. equitans*. Note the distinct cell wall. Cells of *N. equitans* are about 0.4 μm in diameter.

genomes yet sequenced (◀ Table 10.1). Genes for several important metabolic functions are missing from the *N. equitans* genome, including those for the biosynthesis of amino acids, nucleotides, coenzymes, and lipids. Also missing are genes encoding proteins for widely distributed catabolic pathways, such as glycolysis. Presumably, all of these functions are carried out for *N. equitans* by its *Ignicoccus* host, with transfer of needed substances from *Ignicoccus* to the attached *N. equitans* cells. *N. equitans* also lacks some of the genes necessary to encode ATPase, and this indicates that it may not synthesize a functional ATPase. If true, this would be the only cellular organism that lacks ATPase. If no ATPase is present and substrate-level phosphorylation does not occur (because a glycolytic pathway is lacking), then *N. equitans* would be dependent on *Ignicoccus* for energy as well as carbon.

With so many genes missing, which genes remain in the *N. equitans* genome? *N. equitans* contains genes encoding the key enzymes for DNA replication, transcription, and translation as well as genes for DNA repair enzymes. In addition to its small size, the genome of *N. equitans* is also among the most gene dense of any organism known, as over 95% of the *N. equitans* chromosome encodes proteins—a value higher than that of most all other prokaryotic cells (◀ Section 10.3).

The DPANN Superphylum

Metagenomic analyses of numerous habitats have identified diverse archaeal phyla based on their genome sequences (see Section 17.8). Many of these phyla affiliate phylogenetically with *Nanoarchaeota* in the **DPANN superphylum** (Figure 17.1). This large cluster of *Archaea* is named for the phyla *Diapherotrites*, *Parvarchaeota*, *Aenigmarchaeota*, *Nanohaloarchaeota*, and *Nanoarchaeota*, although recently additional phyla have been discovered to reside in this group. These *Archaea* escaped detection for so long because their 16S ribosomal RNA genes are so highly divergent from those of other *Archaea* that they were not recovered using standard metagenomic techniques for surveys of 16S rRNA genes in the environment (▶ Section 19.8 and Figure 19.21).

Members of the DPANN superphylum, like *N. equitans*, appear to be extremely small cells that have highly reduced genomes. Most have very limited metabolic capabilities lacking many core

biosynthetic pathways such as those for the synthesis of certain nucleotides, amino acids, and lipids. The DPANN *Archaea* are predicted to have obligately dependent lifestyles relying on other *Archaea* or *Bacteria* to provide them with the metabolites they need to survive. Like *N. equitans*, many of the DPANN *Archaea* are likely to be symbiotic or parasitic, living on or within other cells. Sequence analyses of complete or nearly complete DPANN genomes recovered from natural samples suggest that these organisms are obligate anaerobes that rely on fermentative forms of metabolism. DPANN *Archaea* have been observed in a wide range of environments including extreme environments (geothermal, acidic, and hypersaline), temperate environments (lake and marine sediments), and the deep subsurface (▶ Section 20.8 and Figure 20.16).

Check Your Understanding

- Which aspects of the biology of *Nanoarchaeum equitans* make it especially interesting from an evolutionary point of view?
- Why can it be said that *N. equitans* is both a carbon and an energy parasite?

17.7 Korarchaeota, the “Secret Filament”

KEY GENUS: *Korarchaeum*

Ribosomal RNA sequences of *Korarchaeota* (Figure 17.1) have been retrieved from a range of geothermal habitats, both submarine and terrestrial. However, *Korarchaeum cryptofilum*, whose name means “the secret filament of youth,” is the only characterized species in the phylum *Korarchaeota*.

First observed as a 16S ribosomal RNA gene phylotype (▶ Figures 19.16 and 19.17) recovered from Obsidian Pool, a hot spring in Yellowstone National Park, USA, *K. cryptofilum* has yet to be grown in pure culture. However, its genome sequence has been determined from metagenomic analyses of a highly enriched culture. *K. cryptofilum* is an obligately anaerobic chemoorganotroph and a hyperthermophile, growing at 85°C. Cells are long, thin (<0.2- μm diameter) filaments of variable length (Figure 17.18a–c), with most filaments being around 15 μm long but some reaching as much as 100 μm . Filaments of *K. cryptofilum* have a tough paracrystalline S-layer (Figure 17.18d), which maintains cell integrity in its extremely hot habitat.

Though *K. cryptofilum* cannot be grown in isolation, its genome sequence provides clues about its lifestyle. *K. cryptofilum* lacks the ability to perform anaerobic respiration and lives a fermentative lifestyle. Similar to other archaeal hyperthermophiles, *K. cryptofilum* grows by fermentation of peptides or amino acids (see Table 17.4). *K. cryptofilum* lacks many core genes in biosynthesis including the ability to synthesize purines, coenzyme A, and several essential cofactors. Presumably *K. cryptofilum* obtains these essential components from its environment. The inability of *K. cryptofilum* to synthesize molecules essential for its own growth may be explained by the evolution of mutual dependence in microbial communities (◀ Section 13.8 and Figure 13.18). This dependence on other members of the hot spring microbial community for key necessities may also explain why *K. cryptofilum* has not yet been obtained in pure culture.

Phylogenetic analyses indicate affinity between *Thaumarchaeota*, *Crenarchaeota*, and *Korarchaeota* (Figure 17.1). These lineages, along

Figure 17.18 *Korarchaeum cryptofilum*. (a) Fluorescence in situ hybridization (FISH; ► Section 19.5) first identified the morphology of *Korarchaeota* growing in an enrichment culture at 85°C. (b) Phase-contrast image of filaments of *K. cryptofilum*. (c) Scanning electron micrograph of a *K. cryptofilum* filament. (d) Transmission electron micrograph of the surface of a *K. cryptofilum* filament showing the paracrystalline S-layer (◄ Section 2.5). Filaments of *K. cryptofilum* are about 0.17 μm wide and 15 μm long.

with a group called the *Aigarchaeota* (see next section), form a cluster of phyla known as the **TACK superphylum** (Figure 17.1). Like the DPANN superphylum (Section 17.6), many of the species in the TACK superphylum are only known from metagenomic analyses, but such information is often important for piecing together the nutritional secrets of uncultured microbes and obtaining their successful laboratory culture.

Check Your Understanding

- What is the most likely reason that *Korarchaeum cryptofilum* has been difficult to isolate in pure culture?
- What phyla comprise the TACK superphylum?

17.8 Other Cryptic Archaeal Phyla

Advances in DNA sequencing technologies have allowed metagenomic analyses to become almost routine. As powerful DNA sequencing approaches are applied to a wider range of habitats, more and more genomes of unusual *Archaea* are being discovered such as those just discussed in the DPANN and TACK superphyla (Sections 17.6, 17.7). These discoveries have greatly expanded our knowledge of archaeal diversity. Thus far, our only insight into these newly discovered archaeal phyla comes from the analysis of genome data assembled from metagenomes. For most of these groups, no cultures are available and there is little direct evidence pertaining to their physiology or ecology. However, metagenomic data allows us to form many hypotheses.

Asgard Archaea

The **Asgard Archaea** is a large group of related phyla discovered and characterized through metagenomic analyses (► Section 20.8 and Figure 20.16). The first of the Asgard Archaea to be discovered were those in the phylum *Lokiarchaeota*. *Lokiarchaeota* were discovered through metagenomic analyses of microbial communities that inhabit deep marine sediments near a highly sulfidic hydrothermal

vent system known as Loki's Castle (Figure 17.19a), located along the Mid-Atlantic Ridge between Greenland and Norway. Remarkably, the genomes of *Lokiarchaeota* contain a number of *eukaryotic* signature genes; in particular, genes associated with membrane remodeling and the development of a cellular cytoskeleton. These results suggest that features uniquely associated with the eukaryotic cell may also be found within the domain *Archaea*. The presence of these eukaryotic-like genes in *Lokiarchaeota* also support well-established findings that the processes of transcription and translation in *Archaea* bear greater resemblance to those in *Eukarya* than to those in *Bacteria* (◄ Section 6.6).

Since the discovery of the *Lokiarchaeota*, related *Archaea* have been found in many marine and freshwater sediments as well as in geothermal systems. These organisms have been given the phylum names *Thorarchaeota*, *Heimdallarchaeota*, and *Odinarchaeota* after the legendary names of Norse gods. Together, these *Archaea* comprise the **Asgard Archaea**. Like the *Lokiarchaeota*, the genomes of other Asgard Archaea show many features that were once thought to be uniquely eukaryal. And, since Asgard Archaea diverge deeply within the domain *Archaea* (Figure 17.1), it has been hypothesized that they are close relatives of *Eukarya*. Thus far we know relatively little about these mysterious organisms, although their genomes point to an anaerobic and fermentative lifestyle similar to some cultured *Archaea* and many *Archaea* known only from their genomes.

Aigarchaeota and Bathyarchaeota

As with the Asgard Archaea, all of our knowledge of *Aigarchaeota* and *Bathyarchaeota* comes from genomes assembled from metagenomic data. The *Aigarchaeota* (Figure 17.1) belong to the TACK superphylum. The first characterized genome from this group came from "*Candidatus* Caldiarchaeum subterraneum," identified in a metagenome obtained from geothermally heated water found in a Japanese gold mine deep underground. Additional genomes have been identified from other geothermal systems including hot springs. For example, in the hot water runoff channel of a Yellowstone hot spring where *Thermocrinis*, a hyperthermophilic species of *Bacteria*

Figure 17.19 *Lokiarchaeota* and *Aigarchaeota*.

(a) Loki's Castle, an ocean floor hydrothermal vent system at the Mid-Atlantic Ridge (depth, 2350 m). These vent chimneys are rich in iron-sulfide minerals, and when they were active, emitted water at nearly 300°C; the white areas on the surface of the mounds contain elemental sulfur and sulfur-oxidizing bacteria (see also Figure 13.11). The first genomes of *Lokiarchaeota*

(Asgard *Archaea*, Figure 17.1) were assembled from metagenomic analyses of the microbial community living near this hydrothermal vent. (b) The “pink streamer” microbial community that develops at pH 8 and 82°C in the outflow channel of Octopus Spring, Yellowstone National Park, contains the bacterium *Thermocrinis* (◀ Section 16.19) and several *Archaea*. The mass of pink streamers is about 10 cm in diameter.

(c) In a sample of the Octopus Spring streamers subjected to fluorescence in situ hybridization (FISH) analysis (▶ Section 19.5), a cell of *Aigarchaeota* (about 15 μm long) stains pink while cells of *Thermocrinis* stain green. Photos in (b) and (c) taken by J. Beam and W. Inskeep under research permits YELL-2012-SCI-5068 (for part b) and YELL-2013-SCI-5068 (for part c).

4

UNIT

(◀ Section 16.19), forms pink-colored “streamers” (Figure 17.19b; see also Figure 16.52), a species of *Aigarchaeota* has been found that grows enmeshed in the *Thermocrinis* biomass. Although not yet cultured, this organism, given the name “*Candidatus* Calditenuis aerorheumensis” has been identified directly in natural samples using FISH probes (▶ Section 19.5). The probes revealed an organism that is a short filament (Figure 17.19c), and metagenomic analyses suggest that it is an aerobic chemoorganotroph capable of using a variety of organic compounds as energy sources including acetate, sugars, and fatty and amino acids and that it requires a number of vitamins and cofactors.

The *Bathyarchaeota* (Figure 17.1) are also members of the TACK superphylum. The first genomes from this phylum were discovered in metagenomes retrieved from deep-sea sediments. Additional genomes have been obtained from a range of freshwater and shallow marine sediments as well as subsurface habitats. Several genomes of *Bathyarchaeota* contain genes encoding enzymes of the reductive acetyl-CoA pathway. This pathway is used by a wide variety of microbes for CO₂ fixation, acetogenesis, and methanogenesis (◀ Section 14.14 and Figure 14.34). It has been hypothesized that some *Bathyarchaeota* are indeed methanogens, although this remains to be proven. The genomes of *Bathyarchaeota* that have been characterized suggest this phylum likely contains a diversity of metabolic types, including some species capable of degrading complex polymers as well as others that might metabolize C₁ compounds (methylotrophy, ◀ Section 14.16).

- What technique has led to the recent discovery and characterization of many new phyla of *Archaea*?

III • Crenarchaeota

The phylum *Crenarchaeota* contains many cultured isolates, most of which are thermophiles or hyperthermophiles that use sulfur compounds as either electron donors or electron acceptors to thrive in their punishing environments.

Among *Archaea* in laboratory culture, the *Crenarchaeota* are mostly hyperthermophiles and include species growing optimally above the boiling point of water. Many hyperthermophiles are chemolithotrophic autotrophs, and because no phototrophs can survive such temperatures, these organisms are the sole primary producers in these habitats.

17.9 Habitats and Energy Metabolism of *Crenarchaeota*

Most hyperthermophilic *Archaea* have been isolated from geothermally heated soils or waters containing S⁰ and H₂S, and most species metabolize sulfur in one way or another. In terrestrial environments, sulfur-rich springs, boiling mud, and soils may have temperatures up to 100°C and are mildly to extremely acidic owing to the production of sulfuric acid (H₂SO₄) from the biological oxidation of H₂S and S⁰ (◀ Section 14.7 and ▶ Section 21.4). Such hot, sulfur-rich environments, called **sofataras**, are found throughout the world (Figure 17.20), including Italy, Iceland, New Zealand, and Yellowstone National Park in Wyoming. Depending on the surrounding geology, sofataras can be mildly acidic to slightly alkaline (pH 5–8) or extremely acidic, with pH values below 1. Hyperthermophilic crenarchaeotes have been obtained from all of these environments, but most inhabit neutral or weakly acidic thermal habitats.

Figure 17.20 Terrestrial habitats of hyperthermophilic *Archaea*: Yellowstone National Park. (a) A typical solfatara; steam rich in H_2S rises to the surface. (b) Sulfur-rich hot spring, a habitat containing dense populations of *Sulfolobus*. The acidity in solfataras and sulfur springs comes from the oxidation of H_2S and S^0 to H_2SO_4 (sulfuric acid) by *Sulfolobus* and related sulfur-oxidizing microbes. (c) A typical neutral pH boiling spring, Imperial Geyser. Many different species of hyperthermophilic *Archaea* may reside in such a habitat. (d) An acidic iron-rich geothermal spring, another *Sulfolobus* habitat; here the oxidation of Fe^{2+} to Fe^{3+} generates acidity (► Section 22.2 and Figure 22.4c).

Hyperthermophilic *Crenarchaeota* also inhabit undersea hot springs called **hydrothermal vents**. We discuss the geology and microbiology of these fascinating microbial habitats in Section 20.16. Here we only note that submarine waters can be much hotter than surface waters because the water is under hydrostatic pressure. Indeed, all hyperthermophiles with growth temperature optima above 100°C originate from submarine sources. These sources include shallow (2–10 m depth) vents such as those off the coast of Vulcano, Italy, as well as deep (2000–4000 m depth) vents near ocean-spreading centers (see Figure 17.26). Deep hydrothermal vents are the hottest habitats so far known to yield viable life forms.

Most hyperthermophilic *Crenarchaeota* are obligate anaerobes. Their energy-yielding metabolism is either chemoorganotrophic or chemolithotrophic (or both, for example, in *Sulfolobus*) and is dependent on diverse electron donors and acceptors. Fermentation is rare and most bioenergetic strategies employ anaerobic respiration (Table 17.4). Energy is conserved during these respiratory processes by the same general mechanism widespread in *Bacteria*: electron transfer within the cytoplasmic membrane leading to the

formation of a proton motive force from which ATP is made by way of proton-translocating ATPases (◄ Sections 3.8–3.10).

A variety of metabolisms are practiced by crenarchaeotes, and all of these were discussed in Chapter 14. For example, many hyperthermophilic crenarchaeotes grow chemolithotrophically under anoxic conditions with H_2 as the electron donor and S^0 or NO_3^- as the electron acceptor; a few can also oxidize H_2 aerobically (Table 17.4). H_2 respiration with ferric iron (Fe^{3+}) as electron acceptor also occurs in several hyperthermophiles. Other chemolithotrophic lifestyles include the oxidation of S^0 and Fe^{2+} aerobically or Fe^{2+} anaerobically with NO_3^- as the acceptor, and a variety of organic compounds are oxidized by one or another species of crenarchaeote (Table 17.4). Only one sulfate-reducing hyperthermophile is known (the euryarchaeote *Archaeoglobus*, Section 17.4). The only bioenergetic option apparently absent from hyperthermophilic crenarchaeotes is photosynthesis, a means of energy conservation that is apparently limited to temperatures below 74°C (see Figure 17.30). In the next two sections we will meet some of these fascinating microbes, microbes that have contributed significantly to our understanding of the physiochemical limits to life.

17.10 *Crenarchaeota* from Terrestrial Volcanic Habitats

KEY GENERA: *Sulfolobus*, *Acidianus*, *Thermoproteus*, *Pyrobaculum*
Terrestrial volcanic habitats can have temperatures as high as 100°C and are thus suitable for hyperthermophilic *Archaea*. Two phylogenetically related organisms isolated from these environments are *Sulfolobus* and *Acidianus*. These genera form the heart of an archaeal order called the *Sulfolobales* (Table 17.5). In addition, *Sulfolobus* has been a model organism for molecular biology studies of *Archaea*.

Sulfolobales

Sulfolobus grows in sulfur-rich acidic thermal areas (Figure 17.20) at temperatures up to 90°C and at pH values of 1–5. Species of *Sulfolobus* are typically aerobic chemoorganotrophs, though some can also grow as chemolithotrophs by oxidizing H₂S or S⁰ to H₂SO₄ and fixing CO₂. Cells of *Sulfolobus* are more or less spherical but contain distinct lobes

(Figure 17.21a). Cells adhere tightly to sulfur crystals, where they can be seen with a microscope after staining with fluorescent dyes (◀ Figure 14.19b). Besides the aerobic respiration of sulfur or organic compounds, some *Sulfolobus* can also oxidize Fe²⁺ to Fe³⁺, and this ability has been harnessed for the high-temperature leaching of iron and copper ores (▶ Sections 21.6 and 22.1 and 22.2).

A facultative aerobe resembling *Sulfolobus* also lives in acidic solfataric springs. This organism, *Acidianus* (Figure 17.21b), differs from *Sulfolobus* most clearly by its ability to grow using S⁰ both anaerobically as well as aerobically. Under aerobic conditions the organism uses S⁰ as an electron donor, oxidizing S⁰ to H₂SO₄, with O₂ as an electron acceptor. Under anaerobic conditions, by contrast, *Acidianus* uses S⁰ as an electron acceptor with H₂ as the electron donor, forming H₂S as the reduced product. Thus, the metabolic fate of S⁰ in cultures of *Acidianus* depends on the presence or absence of O₂. Like *Sulfolobus*, *Acidianus* is roughly spherical in shape but is not as lobed (Figure 17.21b). It grows at temperatures from 65°C up to a maximum of 95°C. As a group, then, the *Sulfolobales* contain the most thermophilic of all highly acidophilic *Archaea*.

Thermoproteales

Key genera within the *Thermoproteales* are *Thermoproteus*, *Thermofilum*, and *Pyrobaculum*. The genera *Thermoproteus* and *Thermofilum* consist of rod-shaped cells that inhabit neutral or slightly acidic hot springs. Cells of *Thermoproteus* are rigid rods about 0.5 μm in

^bAlso known by the unofficial taxonomic name of “*Geogemma barossii*”.

diameter and highly variable in length, ranging from short cells of 1–2 μm (Figure 17.22a) up to filaments 70–80 μm long. Filaments of *Thermofilum* are thinner, some as little as 0.17–0.35 μm wide, with filament lengths ranging up to 100 μm (Figure 17.22b). Both *Thermoproteus* and *Thermofilum* are strict anaerobes that carry out an S^0 -based anaerobic respiration (Table 17.4). Most

Thermoproteus isolates can grow chemolithotrophically on H_2 or chemoorganotrophically on complex carbon substrates such as yeast extract, small peptides, starch, glucose, ethanol, malate, fumarate, or formate (Table 17.4). *Pyrobaculum* (Figure 17.22c) is a rod-shaped hyperthermophile but is physiologically distinct from other *Thermoproteales* in that some species of *Pyrobaculum* can respire aerobically.

Figure 17.21 Acidophilic hyperthermophilic Archaea, the *Sulfolobales*. (a) *Sulfolobus acidocaldarius*; electron micrograph of a thin section. (b) *Acidianus infernus*; electron micrograph of a thin section. Cells of both organisms vary from 0.8 to 2 μm in diameter. *Sulfolobales* typically show temperature optima below 90°C (Table 17.5).

Figure 17.22 Rod-shaped hyperthermophilic *Archaea*, the *Thermoproteales*. (a) *Thermoproteus neutrophilus*; electron micrograph of a thin section. A cell is about 0.5 μm in diameter. (b) *Thermofilum librum*. A cell is about 0.25 μm in diameter. (c) *Pyrobaculum aerophilum*. Transmission electron micrograph of a thin section; a cell measures 0.5 $\times$ 3.5 μm . Although the temperature optimum of *P. aerophilum* is 100°C, optima for other *Thermoproteales* are all below 90°C (Table 17.5).

However, *Pyrobaculum* can also grow by anaerobic respiration with NO_3^- , Fe^{3+} , or S^0 as electron acceptors and H_2 as an electron donor (that is, they can grow chemolithotrophically and autotrophically). Other species of *Pyrobaculum* can grow anaerobically on organic electron donors, reducing S^0 to H_2S . The growth temperature optimum of *Pyrobaculum* is 100°C, and species of this organism have been isolated from both terrestrial hot springs and hydrothermal vents.

17.11 Crenarchaeota from Submarine Volcanic Habitats

KEY GENERA: *Pyrodictium*, *Pyrolobus*, *Ignicoccus*, *Staphylothermus*

We now consider the microbiology of submarine volcanic habitats, homes to the most thermophilic of all known *Archaea*. These habitats include both shallow-water thermal springs and deep-sea hydrothermal vents. We discuss the geology of these fascinating microbial habitats in Section 20.16 and the interesting animal communities that develop there in Section 23.11. The organisms to be described here constitute an order of *Archaea* called the *Desulfurococcales* (Table 17.5).

Pyrodictium and *Pyrolobus*

Pyrodictium and *Pyrolobus* are examples of microorganisms whose growth temperature optimum lies above 100°C; the optimum for *Pyrodictium* is 105°C and for *Pyrolobus* is 106°C. Cells of *Pyrodictium* are irregularly disk-shaped and grow in culture in a mycelium-like layer attached to crystals of S^0 . The cell mass consists of a network of fibers to which individual cells are attached (Figure 17.23a). The fibers are hollow and consist of protein arranged in a fashion similar to that of bacterial flagella (◀ Section 2.9). However, the filaments do not function in motility but instead as organs of attachment. The cell walls of *Pyrodictium* are composed of glycoprotein. Physiologically, *Pyrodictium* is a strict anaerobe that grows chemolithotrophically on H_2 as an electron donor and S^0 as an electron acceptor (◀ Section 14.12) or chemoorganotrophically on complex mixtures of organic compounds (Table 17.4).

Pyrolobus fumarii (Figure 17.23c) is one of the most thermophilic of the hyperthermophiles. Its growth temperature maximum is 113°C (Table 17.5). *P. fumarii* lives in the walls of “black smoker” hydrothermal vent chimneys (▶ Section 20.16 and Figures 20.43, 20.44, and 20.46) where its autotrophic abilities contribute organic carbon to this otherwise inorganic environment. *P. fumarii* cells are coccoid-shaped (Figure 17.23c), and the cell wall is composed of protein. The organism is an obligate H_2 chemolithotroph, growing by the oxidation of H_2 coupled to the reduction of NO_3^- to ammonium (NH_4^+), thiosulfate ($\text{S}_2\text{O}_3^{2-}$) to H_2S , or very low concentrations of O_2 to H_2O . Besides its extremely thermophilic nature, *P. fumarii* can withstand temperatures substantially above its growth temperature maximum. For example, cultures of *P. fumarii* survive autoclaving (121°C, ▶ Section 4.17) for 1 h, a condition that even bacterial endospores (◀ Section 2.8) cannot withstand.

Another organism in this group shares with *Pyrolobus* a growth temperature optimum of 106°C. However, “Strain 121,” as this organism has been called, actually shows weak growth at 121°C, and cells remain viable for 2 h at 130°C. Only *Methanopyrus*, a hyperthermophilic methanogen, can grow at a higher temperature (122°C, Section 17.2). Strain 121 consists of coccoid cells that are motile by rotating archaella (Figure 17.23d); the organism is also a strict anaerobe and grows chemolithotrophically and autotrophically with Fe^{3+} as electron acceptor and formate or H_2 as electron donors. Thus, it is clear that the *Pyrodictium*/*Pyrolobus* group collectively contains many of the most hyperthermophilic examples of all known microbes.

Desulfurococcus and *Ignicoccus*

Other notable members of the *Desulfurococcales* include *Desulfurococcus*, the genus for which the order is named (Figure 17.24a), and *Ignicoccus*. *Desulfurococcus* is a strictly anaerobic S^0 -reducing organism like *Pyrodictium*, but differs from this organism in its phylogeny and the fact that it is much less thermophilic, growing optimally at about 85°C.

Ignicoccus species grow optimally at about 90°C, and their energy metabolism is based on H_2 as an electron donor and S^0 as an electron acceptor, as is that of so many hyperthermophilic *Archaea* (Table 17.4). Some *Ignicoccus* species are hosts to the small parasitic archaeon *Nanoarchaeum equitans* (Section 17.6). *Ignicoccus*

Figure 17.23 *Desulfurococcales* with growth temperature optima $> 100^{\circ}\text{C}$. (a) *Pyrodictium occultum* (growth temperature optimum, 105°C), dark-field micrograph. (b) Thin-section electron micrograph of *P. occultum*. Cells are highly variable in diameter from 0.3 to $2.5\ \mu\text{m}$. (c) Thin section of a cell of *Pyrolobus fumarii*, one of the most thermophilic organisms ever described (growth temperature optimum, 106°C); a cell is about $1.4\ \mu\text{m}$ in diameter. (d) Negative stain of a cell of “Strain 121,” capable of growth at 121°C ; a cell is about $1\ \mu\text{m}$ wide. Although the *Desulfurococcales* contain the greatest number of hyperthermophiles capable of growth above 100°C , the most thermophilic of all known *Archaea* is actually a euryarchaeote, *Methanopyrus* (Section 17.2).

(Figure 17.24b) has a novel cell structure that lacks an S-layer and possesses a unique *outer cellular membrane*. This outer cellular membrane is distinct in several ways from the outer membrane of gram-negative *Bacteria* (◀ Section 2.4). Most notably, the outer cellular membrane of *Ignicoccus* contains ATPase and is the site of energy conservation. *Ignicoccus* also contains an inner cellular membrane that contains the cytoplasm and the enzymes responsible for biosynthesis and information processing. In this way neither the outer nor inner cellular membrane satisfies the typical definition of a cytoplasmic membrane (◀ Section 2.1).

Between the inner and outer cellular membranes of *Ignicoccus* is a large *intermediate compartment* that is analogous to the periplasm of gram-negative *Bacteria* but is much larger in volume, representing some two to three times the volume of the cytoplasm (Figure 17.24b). The periplasm of *Ignicoccus* also contains membrane-bound vesicles

(Figure 17.24b) that may function in exporting substances outside the cell. In this way, the cell structure of *Ignicoccus* resembles that of *Eukarya*. Because of this, *Ignicoccus* has been proposed to be a modern descendant of the ancestral cell type that gave rise to the origin of eukaryotic cells, a topic we covered earlier (◀ Section 13.4 and Figure 13.10).

Staphylothermus

A morphologically unusual member of the order *Desulfurococcales* is the genus *Staphylothermus* (Figure 17.25). Cells of *Staphylothermus* are spherical, about $1\ \mu\text{m}$ in diameter, and form aggregates of up to 100 cells, much like its morphological but mesophilic counterpart among the *Bacteria*, *Staphylococcus* (◀ Figure 16.20 and ▶ Figure 31.28). Unlike many hyperthermophiles, *Staphylothermus* is not a chemolithotroph

(a)

(b)

Figure 17.24 *Desulfurococcales* with growth temperature optima < 100°C.

(a) Thin section of a cell of *Desulfurococcus saccharovorans*; a cell is 0.7 μm in diameter. (b) Thin section of a cell of *Ignicoccus islandicus*; the cell proper is surrounded by an extremely large periplasmic compartment. The cell itself measures about 1 μm in diameter and the cell plus periplasm measures 1.4 μm . *Ignicoccus* is a host for the tiny parasitic microbe *Nanoarchaeum* (see Figure 17.17).

but instead a chemoorganotroph, with species that grow optimally at 92°C. Organic carbon sources are used as electron donors in sulfur reduction, producing H_2S , acetate, and isovalerate as products (Table 17.4).

Isolates of *Staphylothermus* have been obtained from both shallow marine hydrothermal vents and very hot black smokers (see Figure 17.26; ► Section 20.16). This organism is apparently widely distributed in submarine thermal areas, where it is likely to play a significant role in consuming proteins released from dead organisms.

IV • Evolution and Life at High Temperature

The ancestor of all *Archaea* was likely a hyperthermophile, and virtually all such organisms are *Archaea*. Hyperthermophilic *Archaea* have several biochemical adaptations that make life possible at high temperatures, and the widespread use of H_2 in their metabolisms may reflect early Earth conditions.

Most of the hyperthermophiles discovered so far are species of *Archaea* and some grow near to what may be the upper temperature limit for life. Here we consider the major factors that likely define the upper temperature limit for life and the biological adaptations of hyperthermophiles that permit them to exist at the exceptionally high temperatures of 100°C and higher. We end with a discussion of the importance of hydrogen (H_2) metabolism to the biology of hyperthermophiles.

17.12 An Upper Temperature Limit for Microbial Life

Habitats that contain liquid water—a prerequisite for cellular life—and that have temperatures higher than 100°C are only found where geothermally heated water flows out of vents or rifts in the ocean floor (◀ Figure 13.3 and ► Figures 20.43 and 20.44). The hydrostatic pressure that overlies the water keeps it from boiling, allowing it to reach temperatures of up to about 400°C in vents at several thousand meters' depth. In contrast, terrestrial hot springs can boil and therefore only attain temperatures near 100°C. It is not surprising, then,

that hydrothermal vents have been rich sources of hyperthermophilic *Archaea* with growth temperature optima above 100°C (Table 17.5).

Black smokers emit hydrothermal vent fluid at 250–350°C or higher. Metallic mounds or more upright structures called *chimneys* form from the metal sulfides that precipitate out of the hot fluid as it mixes with the surrounding, much cooler seawater (Figure 17.19a and Figure 17.26). As far as is known, the superheated vent water itself is sterile. However, hyperthermophiles thrive in mounds or smoker chimney walls where temperatures are compatible with their survival and growth (► Figures 20.45 and 20.46). By studying structures such as these, we can address the question, “What is the upper temperature for microbial (and presumably all forms of) life?”

What Is the Upper Temperature Limit for Life?

How high a temperature can hyperthermophiles withstand? Over the past several decades, the known upper temperature limit for life has been pushed higher and higher with the isolation and characterization of new species of thermophiles and hyperthermophiles (Figure 17.27). For some time the record holder was *Pyrolobus fumarii* (Figure 17.23c), with its upper temperature limit for growth of 113°C. The current record holder, *Methanopyrus* (Section 17.2 and Figure 17.8), however, has pushed the limit somewhat higher, with the ability to grow at 122°C and to survive substantial periods at even higher temperatures. Given the trend over the past several years (Figure 17.27), one can predict that *Archaea* even more hyperthermophilic than *Methanopyrus* may inhabit hydrothermal environments but have yet to be isolated. Indeed, many experts predict that the upper temperature limit for *Archaea* is likely to exceed 140°C, perhaps even 150°C, and that the maximum temperature allowing survival but not growth is hotter yet.

Biochemical Problems at Supercritical Temperatures

Whatever the upper temperature limit is for life, it is likely to be defined by one or more biochemical challenges that evolution has been unable to solve. There is obviously an upper limit, but we do

Figure 17.26 Hydrothermal vents. Hydrothermal mound from the Rainbow vent field, Mid-Atlantic Ridge hydrothermal system. The hydrothermal fluid emitting from the two short chimneys is > 300°C and rich in sulfidic minerals.

Figure 17.27 Thermophilic and hyperthermophilic *Bacteria* and *Archaea*. The graph gives the species that were, in turn, the record holders for growing at the highest temperature, from before 1960 to the present.

not yet know what it is. Water samples taken directly from superheated (>250°C) hydrothermal vent discharges are devoid of measurable biochemical markers (DNA, RNA, and protein) that would signal life as we know it, while vents emitting water at temperatures below about 150°C yield evidence of macromolecules. These results are consistent with laboratory experiments on the stability of key biomolecules. For example, ATP is degraded almost instantly at 150°C. Thus, above 150°C, any life forms would have to deal with the heat lability of a molecule that is, as far as is known, a universal energy currency in all cells.

This conclusion has a caveat, however, in that it is possible that the stability of small molecules such as ATP may be significantly greater under cytoplasmic conditions of high levels of dissolved solutes than in pure solutions tested in the laboratory. Nevertheless, if life forms exist at temperatures above 150°C, they must be unique in at least one of two ways—they must either produce novel biomolecules absent from cells as we know them or deploy protective systems that maintain known cellular molecules in a sufficiently stable state to support biochemistry. Only time and more microbiological research and exploration for new organisms growing at ever higher temperatures will reveal which of these possibilities (or perhaps some of both) is correct.

Check Your Understanding

- Where would you expect to find hyperthermophiles that grow at temperatures above 100°C? Why would it be impossible for organisms to grow at 200 or 300°C?

17.13 Molecular Adaptations to Life at High Temperature

Because all cellular structures and activities are affected by heat, hyperthermophiles are likely to exhibit multiple adaptations to the exceptionally high temperatures of their habitats. Here we briefly examine some adaptations employed by hyperthermophiles to protect their proteins and nucleic acids at high temperatures.

Protein Folding and Thermostability

Because most proteins denature at high temperatures, much research has been done to identify the properties of thermostable proteins. Protein thermostability derives from the folding of the molecule itself (◀ Figure 6.29), not because of the presence of any special amino acids. Perhaps surprisingly, however, the amino acid composition of thermostable proteins is not particularly unusual except perhaps in their slight bias for increased levels of amino acids that promote alpha-helical secondary structures. In fact, many enzymes from hyperthermophiles contain the same major structural features in both primary and higher-order structure (◀ Section 6.7) as their heat-labile counterparts from organisms that grow best at much lower temperatures.

Thermostable proteins typically do display some structural features that likely improve their thermostability. These include having highly hydrophobic cores, which decrease the tendency of the protein to unfold in an ionic environment, and more ionic interactions on the protein surfaces, which also help hold the protein together and work against unfolding. Ultimately, it is the *folding* of the protein that most affects its heat stability, and noncovalent ionic bonds called *salt bridges* on a protein's surface likely play a major role in maintaining the biologically active structure. But, as previously stated, many of these changes are possible with only minimal changes in primary structure (amino acid sequence), as seen when thermostable and heat-labile forms of the same protein are compared.

Chaperones: Assisting Proteins to Remain in Their Native State

Earlier we discussed a class of proteins called *chaperones* (heat shock proteins; ▶ Section 6.11) that function to refold partially denatured proteins. Hyperthermophilic *Archaea* have special classes of chaperones that function only at the highest growth temperatures. In cells of *Pyrodictium abyssi* (Figure 17.28), for example, a major chaperone is the protein complex called the **thermosome**. This complex keeps other proteins properly folded and functional at high temperature, helping cells survive even at temperatures above their maximal growth temperature. Cells of *P. abyssi* grown near its maximum temperature (110°C) contain high levels of the thermosome. Possibly because of this, the cells can remain viable following a heat shock, such as a 1-h treatment in an autoclave (121°C). In cells experiencing such a treatment and then returned to the optimum temperature, the thermosome, which is itself quite heat resistant, is thought to refold sufficient copies of key denatured proteins that *P. abyssi* can once again begin to grow and divide. Thus, as a result of chaperone activity, the upper temperature limit at which many hyperthermophiles can *survive* is higher than the upper temperature

Figure 17.28 *Pyrodictium abyssi*, scanning electron micrograph. *Pyrodictium* has been studied as a model of macromolecular stability at high temperatures. Cells are enmeshed in a sticky glycoprotein matrix that binds them together.

at which they can *grow*. The “safety net” of chaperone activity probably ensures that cells in nature that briefly experience temperatures above their growth temperature maximum are not killed by the exposure.

DNA Stability: Solutes, Reverse Gyrase, and DNA-Binding Proteins

What keeps DNA from melting at high temperatures? Various mechanisms are known to contribute. One such mechanism increases cellular solute levels, in particular potassium (K^+) or compatible organic compounds. For example, the cytoplasm of the hyperthermophilic methanogen *Methanopyrus* (Section 17.2) contains greater than 1 M potassium cyclic 2,3-diphosphoglycerate. This solute prevents chemical damage to DNA, such as depurination or depyrimidization (loss of a nucleotide base through hydrolysis of the glycosidic bond) from high temperatures, events that can lead to mutation (◀ Section 9.2). This compound and other compatible solutes such as potassium di-*myo*-inositol phosphate, which protects against osmotic stress, and the polyamines putrescine and spermidine, which stabilize both ribosomes and nucleic acids at high temperature, help maintain key cellular macromolecules in hyperthermophiles in their active forms.

A unique protein found *only* in hyperthermophiles is responsible for DNA stability in these organisms. All hyperthermophiles produce a special DNA topoisomerase called **reverse DNA gyrase**. This enzyme introduces positive supercoils into the DNA of hyperthermophiles (in contrast to the negative supercoils introduced by DNA gyrase present in *Bacteria* and most *Archaea*; ▶ Section 6.1). Positive supercoiling stabilizes DNA to heat and thereby prevents the DNA helix from spontaneously unwinding. The noticeable absence of reverse DNA gyrase in organisms whose growth temperature optima lie below 80°C strongly suggests a specific role for this enzyme in DNA stability at high temperatures.

Most *Archaea* also contain highly basic (positively charged) DNA-binding proteins that are remarkably similar in amino acid sequence and folding properties to the core histones of the *Eukarya*

Suzette L. Pereira

Figure 17.29 Archaeal histones. Electron micrograph of linearized plasmid DNA wrapped around copies of archaeal histone Hmf (from the hyperthermophilic methanogen *Methanothermobacter fervidus*) to form the roughly spherical, darkly stained nucleosome structures (arrows). Compare this micrograph with an artist's depiction of the histones and nucleosomes of *Eukarya* shown in Figure 2.43b.

(◀ Figure 2.43b). Archaeal histones from the hyperthermophilic methanogen *Methanothermobacter fervidus* (Figure 17.7c) have been particularly well studied. These proteins wind and compact DNA into nucleosome-like structures (Figure 17.29) and maintain the DNA in a double-stranded form at very high temperatures. Archaeal histones are found in most *Euryarchaeota*, including extremely halophilic *Archaea*, such as *Halobacterium*. However, because the extreme halophiles are not thermophiles, archaeal histones may have other functions besides DNA stability, in particular in assisting in gene expression by opening the helix to allow transcriptional proteins to bind.

Lipid and Ribosomal RNA Stability

How have the lipids and the protein-synthesizing machinery of hyperthermophiles adjusted to high temperatures? Virtually all hyperthermophilic *Archaea* synthesize lipids of the biphytanyl tetraether type (◀ Section 2.1). These lipids are naturally heat resistant because the phytanyl units forming each half of the membrane structure are covalently bonded to one another; this yields a *lipid monolayer* membrane instead of the normal lipid bilayer (◀ Figure 2.3). This structure resists the tendency of heat to pull apart a lipid bilayer constructed of fatty acid or phytanyl side chains that are not covalently bonded.

A final point on molecular adaptations to life at high temperatures is the base composition of ribosomal RNAs. Ribosomal RNAs are key structural and functional components of the ribosome, the cell's protein-synthesizing apparatus (◀ Section 6.10). Hyperthermophilic species of both *Bacteria* and *Archaea* show as much as a 15% greater proportion of G + C base pairs in their small ribosomal subunit RNAs compared with organisms that grow at lower temperatures. G + C base pairs form three hydrogen bonds compared to the two of AU base pairs (◀ Figure 6.1c), and thus the higher G + C content of the ribosomal RNAs should confer greater thermal stability on the ribosomes of these organisms and this should assist protein synthesis at high temperatures. By contrast to

ribosomal RNAs, the G + C content of genomic DNA of hyperthermophiles is often rather low, which suggests that the thermal stability of ribosomal RNA might be an especially significant factor for life under hyperthermophilic conditions.

Check Your Understanding

- How do hyperthermophiles keep proteins and DNA from being destroyed by high heat?
- How are the lipids and ribosomes of hyperthermophiles protected from heat denaturation?

17.14 Hyperthermophilic Archaea, H₂, and Microbial Evolution

When cellular life first arose on Earth nearly 4 billion years ago (◀ Figures 1.10a and 13.1), temperatures almost certainly were far hotter than they are today. Thus, for hundreds of millions of years, Earth may have been suitable only for hyperthermophiles. Given the discussion above on the temperature limits to life, it has been hypothesized that biological molecules, biochemical processes, and the first cells arose on Earth around hydrothermal springs and vents on the seafloor as they cooled to temperatures compatible with biological molecules (◀ Section 13.1 and Figures 13.3 and 13.4). The phylogeny of modern hyperthermophiles (Figure 17.1), as well as the similarities in their habitats and metabolism to those of early cells on Earth, suggests that hyperthermophiles may be the closest remaining descendants of ancient cells and are a living window into the biology of ancient microbial life.

Hyperthermophilic Habitats and H₂ as an Energy Source

The oxidation of H₂ linked to the reduction of Fe³⁺, S⁰, NO₃⁻, or, rarely, O₂ is a widespread mechanism of energy conservation in hyperthermophiles (Table 17.4 and Figure 17.30). This, coupled with the likelihood that these hyperthermophiles best characterize early Earth phenotypes, points to the important role H₂ has played in the evolution of microbial life. Hydrogen metabolism may have evolved in primitive organisms because of the ready availability of H₂ and suitable inorganic electron acceptors in their primordial environments, but also because known examples of H₂-based energy conservation require relatively few proteins (◀ Figure 13.5). As chemolithotrophs, these organisms may have obtained all of their carbon from CO₂ or might have assimilated available organic compounds directly for biosynthetic needs. Either way, it is likely that the oxidation of H₂ was the energetic driving force for maintaining life processes.

If one compares microbial energy conservation mechanisms as a function of temperature from data of cultured *Bacteria* and *Archaea*, only chemolithotrophic organisms are known at the hottest temperatures (Figure 17.30). Chemoorganotrophy occurs up to at least 110°C, as this is the upper temperature limit for growth of *Pyrodicticum occultum*, an organism that can conserve energy and grow by fermentation and by chemolithotrophic growth on H₂ with S⁰ as electron acceptor (Table 17.4). Photosynthesis is apparently the least heat-tolerant of all bioenergetic processes, with no hyperthermophilic representatives known and an upper temperature limit of 73°C. This is consistent with the conclusion that

Figure 17.30 Upper temperature limits for energy metabolism. The record holder for phototrophy is *Synechococcus lividus* (Bacteria, cyanobacteria); for chemoorganotrophy, *Pyrodictium occultum* (Archaea); for chemolithotrophy with S⁰ as electron donor, *Acidianus infernus* (Archaea); for chemolithotrophy with Fe²⁺ as electron donor, *Ferroglobus placidus* (Archaea); and for chemolithotrophy with H₂ as electron donor, *Methanopyrus kandleri* (Archaea, 122°C).

anoxygenic photosynthesis first appeared on Earth some hundreds of millions of years after the first life forms are thought to have appeared (◀ Figure 13.1).

Comparisons of bioenergetic options as a function of temperature (Figure 17.30) point to the H₂-oxidizing hyperthermophilic *Archaea* and *Bacteria* as the most likely extant examples of Earth's earliest cellular life forms. More so than any other microbes, these organisms retain the metabolic and physiological traits one would predict to be necessary for existence on a hot early Earth.

Check Your Understanding

- What phylogenetic and physiological evidence suggests that today's hyperthermophiles are the closest living links to Earth's earliest cells?
- Which mechanism of energy conservation is least heat tolerant?
- Which chemolithotrophic lifestyle seems best suited to life at the highest temperatures?

Go to **Mastering Microbiology** for videos, animations, practice tests, and more.

CHAPTER REVIEW

I • Euryarchaeota

- 17.1** Extremely halophilic *Archaea* require large amounts of NaCl for growth and accumulate large levels of K⁺ in their cytoplasm as a compatible solute. These salts affect cell wall stability and enzyme activity. The light-mediated proton pump bacteriorhodopsin helps extreme halophiles make ATP.

Q Describe how the light-mediated proton motive force is established in *Halobacterium salinarum*.

- 17.2** Methanogenic *Archaea* are strict anaerobes whose metabolism is linked to the production of CH₄. Methane can be produced by CO₂ reduction by H₂, from methyl substrates such as CH₃OH, or from acetate.

Q What are two unique features of the methanogen *Methanopyrus*?

- 17.3** *Thermoplasma*, *Ferroplasma*, and *Picrophilus* are extremely acidophilic thermophiles that form their own phylogenetic family of *Archaea*. Cells of *Thermoplasma* and *Ferroplasma* lack cell walls, resembling the mycoplasmas in this regard.

Q What two major physiological features unify species of *Thermoplasmatales*? Why does this allow some of them to successfully colonize coal refuse piles?

- 17.4** *Archaeoglobus* and *Ferroglobus* are related anaerobic *Archaea* that carry out different anaerobic respirations. *Archaeoglobus* is a sulfate reducer and *Ferroglobus* is a nitrate reducer that oxidizes ferrous iron.

Q What metabolic property is shared by the archaean *Archaeoglobus* and the bacterium *Desulfovibrio*?

II • Thaumarchaeota and Cryptic Archaeal Phyla

- 17.5** *Thaumarchaeota* are widespread and abundant in soils and marine environments. All cultivated species of thaumarchaea are autotrophic ammonia-oxidizers and these organisms are important in the global nitrogen cycle.

Q What is physiologically unusual about the thaumarchaeotal species *Nitrosopumilus maritimus*?

- 17.6** *Nanoarchaeum equitans* is a hyperthermophile that forms its own phylum, the *Nanoarchaeota*, and is a parasite of the crenarchaeote *Ignicoccus*. *N. equitans* has a tiny, highly compact genome and depends on *Ignicoccus* for most of its cellular needs, including both carbon and energy.

Q What features of *Nanoarchaeota* and other members of the DPANN superphylum distinguish them from other *Archaea*?

- 17.7** *Korarchaeum cryptofilum* forms its own phylum, the *Korarchaeota*, and is a hyperthermophile that lacks important biosynthetic pathways, obtaining key building blocks from its environment.

Q What is a likely explanation for the fact that organisms like *Korarchaeum cryptofilum* have proven so difficult to cultivate in pure culture?

- 17.8** *Lokiarchaeota* and other Asgard Archaea have eukaryotic signature genes that were once thought to be unique to the domain *Eukarya*. *Bathyarchaeota* and *Aigarchaeota* are members of the TACK superphylum known only from their genome sequences obtained from metagenomic studies.

Q What pathway, observed in the genomes of certain *Bathyarchaeota*, has led to the hypothesis that these organisms are capable of acetogenesis or possibly methanogenesis?

III • Crenarchaeota

- 17.9** A wide variety of chemoorganotrophic and chemolithotrophic energy metabolisms have been found in hyperthermophilic *Crenarchaeota*, including fermentation and anaerobic respirations. Strictly autotrophic lifestyles are common, but photosynthesis is absent.

Q What forms of energy metabolism are present in *Crenarchaeota*? What form is not present?

- 17.10** Hyperthermophilic *Crenarchaeota* thrive in terrestrial hot springs of various chemistries. These include in particular organisms such as *Sulfolobus*, *Acidianus*, *Thermoproteus*, and *Pyrobaculum*.

Q What is unusual about the metabolism of S^0 by *Acidianus*?

- 17.11** In deep-sea hydrothermal systems, *Crenarchaeota* such as *Pyrolobus*, *Pyrodictum*, *Ignicoccus*, and *Staphylothermus* thrive.

With the exception of the methanogen *Methanopyrus* (*Euryarchaeota*), species of these genera grow at the highest temperatures of all *Archaea*, in many cases well above the boiling point of water.

Q Why is it likely that organisms such as *Pyrolobus fumarii* are limited to hydrothermal habitats rather than terrestrial hot springs?

IV • Evolution and Life at High Temperature

- 17.12** Life as we know it is probably limited to temperatures below 150°C. Key small molecules, such as ATP, are quickly destroyed above this temperature.

Q What organism is the current record holder for the upper temperature limit for growth? What is predicted to be the absolute upper temperature limit for growth, and why?

- 17.13** Macromolecules in hyperthermophiles are protected from heat denaturation by their heat-stable folding patterns (proteins), solutes and binding proteins (DNA), unique monolayer membrane architecture (lipids), and the high GC content of their ribosomal RNAs.

Q What is reverse DNA gyrase and why is it important to hyperthermophiles?

- 17.14** Hydrogen metabolism is likely to have been the driving force behind the energetics of the earliest cells on Earth. Chemolithotrophic metabolisms based on H_2 as an electron donor are found in the most heat-tolerant of all known *Bacteria* and *Archaea*.

Q Why might H_2 metabolism have evolved as a mechanism for energy conservation in the earliest organisms on Earth?

APPLICATION QUESTIONS

- Using the phylogenetic tree in Figure 17.1 as a guide, discuss what indicates that bacteriorhodopsin may have been a late evolutionary invention and that anaerobic respiration with S^0 as electron acceptor might have been an early evolutionary invention.
- Use Figure 17.1 to make a hypothesis about the distribution of methanogenesis in the domain *Archaea*. When do you think this trait evolved? What evolutionary processes have resulted in the distribution of this trait in the archaeal family tree?

CHAPTER GLOSSARY

Asgard Archaea a large collection of related archaeal phyla including the *Lokiarchaeota*, members of which are notable for containing many eukaryotic signature genes

Bacteriorhodopsin a protein containing retinal that is found in the membranes of certain extremely halophilic *Archaea* and that is involved in light-mediated ATP synthesis

Compatible solute a molecule that is accumulated in the cytoplasm of a cell for adjustment of water activity but that does not inhibit biochemical processes

Crenarchaeota a large phylum of *Archaea* that contains hyperthermophilic organisms

DPANN superphylum a large collection of related archaeal phyla characterized by extremely small cells and reduced genomes, *Nanoarchaeum equitans* is the best-characterized species

Euryarchaeota a large phylum of *Archaea* that contains primarily methanogens, extreme halophiles, *Thermoplasma*, and some marine hyperthermophiles

Extreme halophile a microorganism that requires very large amounts of NaCl for growth, usually greater than 10% and in some cases near saturation, for growth

Extremophiles microorganisms that inhabit environments characterized by extremes of temperature, pH, pressure, or salinity

Halorhodopsin a light-driven chloride pump that accumulates Cl^- within the cytoplasm

Hydrothermal vent a deep-sea hot spring emitting warm ($\sim 20^\circ\text{C}$) to superheated ($>300^\circ\text{C}$) water

Hyperthermophile a species of *Bacteria* or *Archaea* whose growth temperature optimum is 80°C or greater

Korarchaeota a phylum of *Archaea* that contains the hyperthermophile *Korarchaeum cryptophilum*

Methanogen a methane-producing species of the *Archaea*

Nanoarchaeota a phylum of *Archaea* that contains the hyperthermophilic parasite *Nanoarchaeum equitans*

Phytanyl a branched-chain hydrocarbon containing 20 carbon atoms and commonly found in the lipids of *Archaea*

Reverse DNA gyrase a protein universally present in hyperthermophiles that introduces positive supercoils into circular DNA

Solfatara a hot, sulfur-rich, generally acidic environment commonly inhabited by hyperthermophilic *Archaea*

TACK superphylum a large collection of related archaeal phyla including the eponymous *Thaumarchaeota*, *Aigarchaeota*, *Crenarchaeota*, and *Korarchaeota*

Thaumarchaeota a phylum of *Archaea* that contains widespread species capable of aerobic ammonia oxidization

Thermosome a heat shock (chaperone) protein complex that functions to refold partially heat-denatured proteins in hyperthermophiles

Diversity of Microbial *Eukarya* 18

MICROBIOLOGYNOW

Coccolithophores, Engineers of Global Climate

Coccolithophores are single-celled phototrophic eukaryotes. They live near the ocean surface worldwide, where they comprise a large portion of the planktonic community. Coccolithophores (photo inset, cell 6 μm in diameter) have armor plates made of calcium carbonate, formed from autotrophic CO_2 fixation, and often develop immense blooms, dense clouds of cells so large they are visible from space (photo, Barents Sea, July 2016). Coccolithophores play an important role in global climate because their carbonate armor is heavy. It sinks to the ocean floor and is stabilized, eventually forming chalk, a type of sedimentary rock. Chalk deposits worldwide reveal the power of coccolithophores to remove carbon from the atmosphere and turn it into rock. Our ability to predict global climate depends, in part, on how much CO_2 coccolithophores remove from the atmosphere.

The more than 200 species of coccolithophores vary tremendously in their distribution, ecology, and morphology (see Figure 18.15). No one knows for certain why they form armor plates, but we do know that forming these carbonate shells

requires a very large amount of cellular energy. The shells may provide coccolithophores protection from predators or prevent bacterial or virus attachment. Alternatively, the shells might enhance photosynthetic efficiency by functioning as lenses, or in some way trap and concentrate CO_2 . They also might function to protect cells from ultraviolet radiation.

Since coccolithophores vary dramatically in shape, it seems likely that the costs and benefits of shell formation vary from species to species. Climate change is causing elevated CO_2 , higher temperatures, and greater ocean acidity. The former two conditions may enhance coccolithophore growth, whereas the latter should inhibit it. The fate of coccolithophores and their role in determining Earth's future likely depends on their diversity and the costs and benefits of forming their carbonate armor in oceans gradually being transformed by climate change.

I • Organelles and Phylogeny of Microbial *Eukarya*

Microbial *Eukarya* include protists, fungi, and algae. Primary symbioses caused these microbes to acquire mitochondria and red and green algae to also acquire chloroplasts. Many other protists acquired chloroplasts from the uptake of red or green algae in secondary symbioses.

In this chapter, we consider the phylogeny and diversity of microbial eukaryotes. While plants and animals are the most conspicuous members of the *Eukarya*, microbial eukaryotes are far older and more phylogenetically diverse than are their macroscopic relatives. *Eukarya* exhibit tremendous morphological and ecological complexity but a limited range of metabolic diversity. Metabolically, eukaryotic organisms are almost exclusively chemoorganotrophic or phototrophic and most species are obligate aerobes. Nearly all *Eukarya* depend on their organelles—mitochondria and chloroplasts (◀ Section 2.14)—for generating energy. The nutritional lifestyles of microbial eukaryotes are highly varied and include *phagotrophy* (obtaining energy by consuming other cells or detritus), *saprotrophy* (obtaining energy by absorbing organic matter from the environment), *phototrophy* (generating energy from light), and/or *symbiosis* (a persistent interaction with another organism that can be beneficial, commensal, or parasitic, Chapter 23).

Microbial eukaryotes can be defined by their morphology as *protists*, *algae*, or *fungi*. **Protist** is an informal term referring to any eukaryotic microorganism that is not a plant, animal, or fungus. Protists are found in many different phylogenetic lineages of *Eukarya* and are typically phagotrophic, though some are phototrophic. **Algae** include unicellular and multicellular eukaryotes that perform photosynthesis but are not plants. While some algal groups share an ancestor with plants, as we will see shortly, phototrophic microbes have evolved independently in multiple different lineages of *Eukarya*. **Fungi** are nonphototrophic eukaryotic microorganisms with rigid cell walls composed of chitin. The fungi form a single phylogenetic group, which includes yeasts, molds, and mushrooms. Fungi typically exhibit saprotrophic and/or symbiotic lifestyles and are often associated with (primarily aerobic) decomposition.

One thing that unites all *Eukarya* is that their ancestors had complex cell structure and true organelles. The structural complexity of the eukaryotic cell (◀ Sections 2.13–2.15) has allowed the domain *Eukarya* to evolve tremendous morphological diversity. As a result, complex cellular structures and multicellularity are common traits of eukaryotic microorganisms. We begin our consideration of microbial eukaryotes by examining the evolutionary history of the domain *Eukarya* and the endosymbiotic origins of organelles.

18.1 Endosymbioses and the Eukaryotic Cell

The exact evolutionary origin of the eukaryotic cell remains uncertain, but biologists agree that the eukaryotic cell is a genetic chimera containing genes from multiple sources. The last common ancestor of all eukaryotic cells was a single-celled microorganism closely

Figure 18.1 Organellar DNA. Cells of the yeast *Saccharomyces cerevisiae* have been stained with the fluorescent dye DAPI that binds to DNA. Each mitochondrion has two to four circular chromosomes that stain blue with the dye.

related to *Archaea*. This microorganism had certain features common to all eukaryotic cells, including a nucleus, a cytoskeleton, spliceosomes, and a genome with spliceosomal introns (that is, those introns processed by spliceosomes), but it lacked energy-producing organelles—the mitochondria and chloroplasts. These were obtained by endosymbiosis (◀ Section 13.4).

The acquisition of mitochondria was a foundational event in the origin of *Eukarya*. Mitochondria are derived from *Bacteria* and they contain bacterial DNA (Figure 18.1; ◀ Section 2.14). The acquisition of mitochondria and the establishment of eukaryotic cell structure set the stage for the evolution of diverse microbial lineages in addition to complex multicellular organisms such as plants and animals.

Primary Endosymbioses

Endosymbiosis has played a major role in the origin and diversification of *Eukarya*. All *Eukarya* are descended from cells that contained respiratory mitochondria. Mitochondria evolved through endosymbiosis, in which the ancestor of *Eukarya* formed a symbiotic relationship with a bacterial cell capable of respiration (◀ Sections 2.14 and 13.4). This bacterium may have initially invaded the cytoplasm of the eukaryotic cell as an intracellular parasite or it may have been acquired by *phagocytosis*, but for some reason these partners entered into a stable symbiotic relationship. Over time, the bacterial endosymbiont and its eukaryotic partner evolved mutual dependency until they eventually became a single cell, inseparable. This event is considered **primary endosymbiosis** because the bacterial symbiotic partner was acquired directly by the eukaryotic host cell.

All phototrophic eukaryotes—plants and algae—require chloroplasts to perform photosynthesis. Chloroplasts, like mitochondria, were acquired through primary endosymbiosis (Figure 18.2). In this case, a eukaryotic cell, which already contained mitochondria, acquired a phototrophic cyanobacterium as an endosymbiont (◀ Section 13.4). As with the mitochondria, this cyanobacterial endosymbiont evolved mutual dependency with its eukaryotic host until they became inseparable. However, primary endosymbiosis is not the end of the story for the evolution of organelles.

Secondary Endosymbioses

Primary endosymbiosis with a cyanobacterium gave rise to the *Archaeplastida*, a lineage that includes green algae, red algae, and plants (Figure 18.2 and see Figure 18.3). However, following this *primary* endosymbiosis event, several different groups of protists acquired chloroplasts through *secondary endosymbiosis*. **Secondary endosymbiosis** occurs when a cell that already contains an endosymbiont is engulfed by a second host cell (Figure 18.2). For example, many protists became phototrophic by acquiring an *algal endosymbiont* that already contained a chloroplast. Over time, many features of the algal endosymbiont were lost but its chloroplasts remained, as did the ability to perform photosynthesis.

Secondary endosymbiosis has occurred multiple times within *Eukarya*, giving rise to a diversity of phototrophic eukaryotes (Figure 18.2). The chloroplasts of euglenids and chlorarachniophytes were acquired through secondary endosymbiosis with green algae, while those of the *Alveolata* (ciliates, apicomplexans, and

dinoflagellates) and *Stramenopiles* were obtained through secondary endosymbioses with red algae (Figure 18.2 and see Figure 18.3). The ancestral red algal chloroplasts were apparently lost from some lineages, such as the ciliates, or became greatly reduced in size in others, such as the apicomplexans. In some other organisms, such as the dinoflagellates, the red algal chloroplast was replaced altogether with chloroplasts from different algae, including green algae. The legacy of endosymbiosis can be detected even if an endosymbiont is lost, because some endosymbiont genes are transferred to the host and become part of the host genome (◀ Section 13.4); these genes are then revealed when the genome is sequenced.

These many examples of endosymbiotic events underscore the importance of endosymbiosis in the evolution and diversification of microbial eukaryotes. It is unlikely that primary endosymbiotic events occurred only twice in evolutionary history—after all, trial and error is the essence of evolution—and secondary endosymbioses are known to have occurred multiple times in several lineages

Figure 18.2 Endosymbioses. Following primary endosymbiotic association(s) leading to the mitochondrion, primary endosymbioses with phototrophic *Bacteria* led to the red and green algae. Secondary symbioses of green and red algae spread the property of photosynthesis to many independent lineages of protists.

(Figure 18.2). There are even examples of animals that engulf phototrophic protists to carry out photosynthesis for extended periods (► Section 23.13). Indeed, it appears that endosymbioses are a common and ongoing occurrence in the eukaryotic world, conferring obvious metabolic advantages on the eukaryotic partner and perhaps other, not-so-obvious advantages, that remain to be discovered.

Check Your Understanding

- Which was acquired first: chloroplasts or mitochondria?
- Describe how euglenids came to acquire chloroplasts.
- Distinguish between primary and secondary endosymbioses.

18.2 Phylogenetic Lineages of *Eukarya*

Based on conclusions drawn from molecular phylogenetic studies and supported by microfossil discoveries, it appears likely that a major phylogenetic radiation took place rather early in eukaryote evolution. This was likely triggered by the endosymbiotic acquisition of mitochondria, the foundational event in the evolution of the eukaryotic cell. All extant *Eukarya* contain mitochondria, structures homologous to mitochondria, or some genetic trace of these structures. What promoted this primary endosymbiotic event is unknown, but quite possibly it was the accumulation of O₂ in the atmosphere

from cyanobacterial photosynthesis (◀ Figure 13.1). Mitochondria would have improved the ability of the early eukaryotic cell to generate energy, providing eukaryotes a considerable advantage over anaerobic competitors. Somewhat later, another primary endosymbiotic event occurred between eukaryotic cells and cyanobacteria, giving rise to the first algae. This event was followed by a series of secondary endosymbioses (Section 18.1 and Figure 18.2) that gave rise to the diversity of phototrophic eukaryotes we see today.

Eukaryotic Evolution: The Big Picture

Although phylogenies based on ribosomal RNA gene sequences (Chapter 13) confirm the three domains of life—*Bacteria*, *Archaea*, and *Eukarya*—our picture of eukaryotic evolution has changed dramatically with the incorporation of data from whole genome sequences. There are currently five *supergroups* of *Eukarya* (a supergroup is not an official taxon but rather a cluster of related phyla): *Archaeplastida*, the *SAR clade*, *Excavates*, *Amoebozoa*, and *Opisthokonta* (Figure 18.3). The *Archaeplastida* include the entire plant kingdom as well as all red algae, green algae, and glaucophytes; these phototrophic lineages resulted from the primary endosymbiosis of chloroplasts (Figure 18.2). The *Stramenopiles*, *Alveolata*, and *Rhizaria* include highly diverse protists including both heterotrophic and phototrophic species. These three groups share an ancestor and they

Figure 18.3 *Phylogenetic tree of Eukarya.* The tree diagram provides a schematic view of phylogenetic relationships for five of the best-characterized supergroups within the *Eukarya*. Colors are used to identify the supergroups in the tree. Dashed lines indicate both primary endosymbioses of mitochondria and chloroplasts, and the secondary endosymbioses of red and green algae. Protists are common in all eukaryotic lineages except the *Opisthokonta* (*Fungi* and *Animalia*) and the plants.

are classified together into the SAR clade (an acronym for *Stramenopiles*, *Alveolata*, and *Rhizaria*). Where it occurs, phototrophy within these lineages was acquired as a result of secondary endosymbiosis (Figure 18.3 and Section 18.1). *Excavates* are diverse protists, many of which are anaerobic, and some of which have acquired phototrophy as a result of secondary endosymbiosis (Figures 18.2 and 18.3). The *Amoebozoa* include many forms of amoebae and slime molds, though cells with an amoeboid morphology occur in many other lineages of *Eukarya* as well. Finally, the *Opisthokonta* include the well-known kingdoms *Fungi* and *Animalia*.

The phylogenetic tree shown in Figure 18.3 should not be considered the final word on eukaryotic evolution. For example, many phyla of *Eukarya* have been discovered that do not fall neatly within these five groups and their position in the tree of life remains uncertain. For example, the haptophytes (Section 18.7) are an unusual and globally important group of microbes that form their own separate branch deep within the eukaryotic phylogenetic tree (Figure 18.3). New genome sequences continue to be unraveled, new organisms continue to be discovered, and new aspects of eukaryotic biology continue to be revealed. With each new discovery, we shed more light on eukaryotic phylogeny, and hence our understanding of eukaryotic phylogeny will continue to improve as our knowledge grows.

Phylogenetic Insights on Endosymbiosis

As we have seen, endosymbiosis has clearly been an important aspect of eukaryotic evolution, and the acquisition of the mitochondrion by primitive *Eukarya* was central to the evolutionary success of this domain. However, some parasitic microbial eukaryotes such as *Giardia* and *Microsporidia* lack mitochondria. The *Microsporidia* were once thought to be ancient members of the *Eukarya*, descended from an ancestor of *Eukarya* that lacked mitochondria. We now know, however, that these amitochondriate eukaryotes are descended from eukaryotic ancestors that once had mitochondria (see the position of *Microsporidia* in Figure 18.24) but then lost them for some reason, perhaps while reverting to an anaerobic lifestyle such as in *Giardia*, *Entamoeba*, and several other anaerobic parasitic eukaryotes. However, the genomes of amitochondriate eukaryotes typically retain a few genes of mitochondrial origin, and these molecular leftovers are strong evidence that the organisms once had mitochondria.

The tree of *Eukarya* (Figure 18.3) also shows how secondary endosymbioses account for the origin of chloroplasts in some unicellular phototrophic eukaryotes. Following primary endosymbiosis of the cyanobacterial ancestor of chloroplasts by early mitochondrion-containing eukaryotes, these now phototrophic eukaryotes diverged into red and green algae. Then, in secondary endosymbioses, ancestors of the euglenids, kinetoplastids, and chlorarachniophytes engulfed green algae while ancestors of the *Alveolata* and *Stramenopiles* engulfed red algae (Section 18.1). These secondary endosymbioses account for the great phylogenetic diversity of phototrophic eukaryotes, which we explore later in this chapter.

With a feeling for the “big picture” of eukaryotic evolution, we now move on to consider microbial eukaryotes themselves. During our tour, a diverse array of nutritional lifestyles, cellular accessories, interesting habitats, and ecological strategies for survival will unfold.

Check Your Understanding

- What are the five major supergroups within the *Eukarya*?
- What supergroup was formed as a result of the primary endosymbiosis of chloroplasts?
- What group of microbial eukaryotes is most closely related to animals?

II • Protists

The term “protist” describes any microbial eukaryote that is not a plant, animal, or fungus. Protists are highly diverse in their phylogeny, morphology, and ecology, and their metabolisms range from chemoorganotrophic to phototrophic.

With the big picture of eukaryotic phylogeny as our guidepost, we begin with the protists, an enormously diverse group defined loosely by their morphology. Protists include both phototrophic and nonphototrophic microbial eukaryotes, and while most are unicellular, some are multicellular. Protists are widely distributed in nature, exhibit a wide range of morphologies, and show great phylogenetic diversity.

18.3 *Excavates*

KEY GENERA: *Giardia*, *Trichomonas*, *Trypanosoma*, *Euglena*

The *Excavates* are a diverse group of protists including both chemoorganotrophs and phototrophs, with some species being anaerobic. Once considered as a coherent taxonomic group, the *Excavates* include a collection of distantly related organisms whose phylogeny remains controversial. We start with the diplomonads and parabasalids, flagellated protists that *lack* mitochondria and chloroplasts. These microbes live in anoxic habitats, such as animal intestines, either symbiotically or as parasites, and conserve energy from fermentation. Some diplomonads cause serious and common diseases in fish, domestic animals, and humans, and one parabasalid causes a major sexually transmitted disease of humans. Both groups share a relatively recent common ancestor before they diverged to form separate phylogenetic lineages (Figure 18.3).

Diplomonads

Diplomonads (Figure 18.4a) characteristically contain *two nuclei* of equal size, and also contain mitosomes, much reduced mitochondria lacking electron transport proteins and enzymes of the citric acid cycle (◀ Figure 3.12). The diplomonad *Giardia* has a relatively small genome for a eukaryote, about 12 megabase pairs (Mbp). The genome is also quite compact, contains few introns, and lacks genes for many metabolic pathways, including the citric acid cycle. These characteristics likely account for the organism’s parasitic and anaerobic lifestyle. *Giardia intestinalis* (Figure 18.4a), also known as *Giardia lamblia*, causes giardiasis, one of the most common waterborne diarrheal diseases in the United States. We examine human giardiasis in Section 34.4.

Figure 18.4 Diplomonads and parabasalids. (a) Light photomicrograph of cells of *Giardia intestinalis*, a typical diplomonad. Note the dual nuclei. Cells are about 10 μm wide. (b) Light photomicrograph of cells of the parabasalid *Trichomonas vaginalis*. Cells are about 6 μm wide. The spearlike structure (axostyle) is used to attach the cell to urogenital tissues.

Parabasalids

Parabasalids contain a *parabasal body* that, among other functions, gives structural support to the cell's Golgi complex. These anaerobic microbial eukaryotes lack mitochondria but contain *hydrogenosomes*.

Hydrogenosomes are anaerobic organelles that resemble and evolved from mitochondria and produce ATP through fermentation reactions resulting in the production of H_2 and acetate. Parabasalids live in the intestinal and urogenital tract of vertebrates and invertebrates as parasites or as commensal symbionts. The parabasalid *Trichomonas vaginalis* is motile by a tuft of flagella (Figure 18.4b) and causes a widespread sexually transmitted disease in humans (► Section 34.4 and Figure 34.9).

The genomes of parabasalids are unique among eukaryotes in that most of them lack introns, the noncoding sequences characteristic of eukaryotic genes (◄ Sections 6.6 and 10.4). In addition, the genome of *T. vaginalis* is surprisingly huge for a parasitic organism, about 160 Mbp, and includes genes acquired from bacteria by horizontal gene transfer. Much of the genome of *T. vaginalis* contains repetitive DNA sequences and transposable elements (◄ Section 13.9), which has made genomic analyses difficult. But *Trichomonas* is still thought to contain nearly 60,000 genes, about twice that of the human genome and near the upper limit observed thus far for eukaryotic genomes.

Kinetoplastids

Kinetoplastids are a well-studied group of *Excavates* and are named for the presence of the *kinetoplast*, a mass of DNA present in their single, large mitochondrion. Kinetoplastids live primarily in aquatic habitats, where they feed on bacteria. Some species, however, are parasites of animals and cause serious diseases in humans and vertebrate animals. Cells of *Trypanosoma*, a genus of organisms that infect humans, are small, about 20 μm long, thin, and crescent-shaped.

Trypanosomes have a single flagellum that originates in a basal body and folds back laterally across the cell where it is enclosed by a flap of cytoplasmic membrane (Figure 18.5). Both the flagellum and the membrane participate in propelling the organism, making effective movement possible even in viscous liquids, such as blood, where pathogenic trypanosomes are often found.

Trypanosoma brucei (Figure 18.5) causes *African sleeping sickness*, a chronic and usually fatal human disease. The parasite lives and grows primarily in the bloodstream, but in the later stages of the disease it invades the central nervous system, causing an inflammation of the brain and spinal cord that is responsible for the characteristic neurological symptoms of the disease. The parasite is transmitted from host to host by the tsetse fly, *Glossina* spp., a blood-sucking fly found only in certain parts of Africa. After moving from the human to the fly in a blood meal, the parasite proliferates in the intestinal tract of the fly and invades the insect's salivary glands and mouthparts, from which it is transferred to a new human host by a fly bite (► Section 34.6).

Other kinetoplastids that are human parasites include *Trypanosoma cruzi*, the causative agent of *Chagas disease*, and *Leishmania* species, the causative agents of cutaneous and systemic *leishmaniasis*. Chagas disease is spread by the bite of a blood-feeding insect called the “kissing bug.” The disease is usually self-limiting, but it can become chronic and lead to a fatal infection. Leishmaniasis is a disease of tropical and subtropical regions transmitted to humans and other mammals by a bite from the sand fly. This potentially fatal disease can be localized to the skin surrounding a fly bite or can infect the spleen and liver and cause systemic infection. Both Chagas disease and leishmaniasis are covered in more detail in Section 34.6.

Euglenids

Another well-studied group of excavates are the euglenids (Figure 18.6). Unlike the kinetoplastids, these motile microbial eukaryotes are nonpathogenic and are both chemotrophic and phototrophic. Most euglenids contain two flagella, dorsal and ventral, and their active motility allows the organisms to access both illuminated and dark habitats in their environment to support their alternate nutritional lifestyles.

Figure 18.5 Trypanosomes. Photomicrograph of the flagellated kinetoplastids *Trypanosoma brucei*, the causative agent of African sleeping sickness. Blood smear preparation. The cells of *T. brucei* are about 3 μm wide.

Figure 18.6 *Euglena*, a euglenid. (a) This phototrophic protist, like other euglenids, is not pathogenic. A cell is about 15 μm wide. (b) High-magnification view.

Euglenids live exclusively in aquatic habitats, both freshwater and marine, and contain chloroplasts, which support phototrophic growth (Figure 18.6). In darkness, however, cells of *Euglena*, a typical euglenid, can lose their chloroplasts and exist as chemoorganotrophs. Many euglenids can also feed on bacterial cells via **phagocytosis**, a process of surrounding a particle with a portion of their flexible cytoplasmic membrane to engulf the particle and bring it into the cell. The engulfed particle remains in this structure (called the *phagosome*) where it is digested, and the released nutrients are made available to nourish the cell.

- What diseases are caused by *Trypanosoma cruzi*, *Leishmania*, and *Giardia*?
- How do diplomonads obtain energy?

18.4 Alveolata

KEY GENERA: *Gonyaulax*, *Plasmodium*, *Paramecium*

The *Alveolata* as a group are characterized by their *alveoli*, cytoplasmic sacs located just under the cytoplasmic membrane. Although the function of alveoli is unknown, they may help the cell maintain osmotic balance by controlling water influx and efflux, and in the dinoflagellates, they may function as armor plates. Three phylogenetically distinct, although related, kinds of *Alveolata* are known: the *ciliates*, which use cilia for motility; the *dinoflagellates*, which are motile by means of a flagellum; and the *apicomplexans*, which are parasites of humans and other animals (Figure 18.3).

Ciliates

Ciliates possess *cilia* (Figure 18.7) at some stage of their life cycle. Cilia are structures that function in motility and may cover the cell

or form tufts or rows, depending on the species (◀ Section 2.15 and Figure 2.48a). Probably the best-known and most widely distributed ciliates are those of the genus *Paramecium* (Figure 18.7). Like many other ciliates, *Paramecium* use cilia both for motility and to obtain food by ingesting particulate materials such as bacterial cells through a distinctive funnel-shaped oral groove. Cilia that line the oral groove move material down the groove to the cell mouth, also called the *gullet* (Figure 18.7b). Once in the gullet, the material is enclosed in a vacuole by phagocytosis. Digestive enzymes secreted into the vacuole then break down the material as a source of nutrients.

Ciliates are unique among protists in having two kinds of nuclei, *micronuclei* and *macronuclei*. Genes in the macronucleus regulate basic cellular functions, such as growth and feeding, whereas those of the micronucleus are involved in sexual reproduction, which occurs through a partial fusion of two *Paramecium* cells and exchange of micronuclei. The genome of *Paramecium* is huge, with macronuclear genes numbering about 40,000, nearly twice that of humans.

Many *Paramecium* species (as well as many other protists) are hosts for endosymbiotic *Bacteria*, *Archaea*, or eukaryotes, the latter usually green algae. These organisms may play a nutritional role, synthesizing vitamins or other growth factors used by the host cell. Several anaerobic ciliated protists also contain endosymbionts. For example, ciliated protists in the termite hindgut contain endosymbiotic methanogens (*Archaea*) that consume H_2 plus CO_2 to form methane (CH_4). Ciliates themselves can also be symbiotic: Obligately anaerobic ciliates are present in the rumen, the forestomach of ruminant animals, and play an important role in the digestive and fermentative processes of the animal (▶ Sections 23.15 and 23.16).

Figure 18.7 *Paramecium*, a ciliated protist. (a) Phase-contrast photomicrograph. (b) Scanning electron micrograph. Note the cilia in both micrographs. A single *Paramecium* cell is about 60 μm in diameter.

Figure 18.8 *Balantidium coli*, a ciliated protist that causes a dysentery-like disease in humans. The dark blue-stained lobed structure in this *B. coli* cyst obtained from swine intestine is a dividing macronucleus. The cell is about 50 μm wide.

Some ciliates are animal parasites, although this lifestyle is less common in ciliates than in some other groups of protists. The species *Balantidium coli* (Figure 18.8), for example, is primarily an intestinal parasite of domestic animals but occasionally infects the intestinal tract of humans, producing dysentery-like symptoms. Cells of *B. coli* form cysts (Figure 18.8) that promote their transmission in infected food or water.

Dinoflagellates

Dinoflagellates are a diverse group of motile marine and freshwater phototrophic organisms (Figure 18.9) that acquired the capacity to photosynthesize through secondary endosymbioses (Figures 18.2 and 18.3). Eukaryotic flagella (◀ Section 2.15 and Figure 2.48) encircle the cell and impart spinning movements that give dinoflagellates their name (*dinos* is Greek for “whirling”). Dinoflagellates have two flagella of different lengths and with different points of insertion into the cell, transverse and longitudinal. The transverse flagellum is attached laterally, whereas the longitudinal flagellum originates from the lateral groove of the cell and extends lengthwise (see Figure 18.10b). Some dinoflagellates are free-living, whereas others live a symbiotic existence with animals that form coral reefs, obtaining a sheltered and protected habitat in exchange for

Figure 18.9 The marine dinoflagellate *Ornithocercus magnificus* (an alveolate). The cell proper is the globular central structure; the attached ornate structures are called *lists*. A cell is about 30 μm wide.

Figure 18.10 Toxic dinoflagellates (alveolates). (a) Photograph of a “red tide” caused by massive growth of toxin-producing dinoflagellates such as *Gonyaulax*. The toxin is excreted into the water and also accumulates in shellfish that feed on the dinoflagellates. (b) Colorized scanning electron micrograph of a cell of the dinoflagellate *Gonyaulax*. The cell is about 30 μm wide. (c) Scanning electron micrograph of a toxic spore of *Pfiesteria piscicida*; the structure is about 12 μm wide. (d) A fish killed by *P. piscicida*; note the lesions of decaying flesh.

supplying phototrophically fixed carbon as a food source for the reef. A number of free-living species are capable of bioluminescence and emit light when disturbed at night. This bioluminescence results in a “sparkling” effect that can often be observed in coastal seas and bioluminescent bays.

Several species of dinoflagellates are toxic and can cause *harmful algal blooms* (see MicrobiologyNow in the Chapter 15 opener for other toxic microbial blooms). For example, dense suspensions of *Gonyaulax* cells, called “red tides” (Figure 18.10a) because of the red-colored pigments of this organism, can form in warm and typically polluted coastal waters. Such blooms are often associated with fish kills and poisoning in humans following consumption of mussels that have accumulated *Gonyaulax* cells (Figure 18.10b) through filter feeding. Toxicity results from a neurotoxin that can cause a condition called *paralytic shellfish poisoning* in humans and some marine animals, such as sea otters. Symptoms include numbness of the lips, dizziness, and difficulty breathing; in severe cases, death can result from respiratory failure. *Pfiesteria* is another toxic dinoflagellate. Toxic spores of *Pfiesteria piscicida* (Figure 18.10c) infect fish and eventually kill them by way of neurotoxins that affect movement and destroy skin. Lesions form on areas of the fish, allowing opportunistic bacterial pathogens to grow (Figure 18.10d). Symptoms of human toxemia from *Pfiesteria* poisoning include skin rashes and respiratory problems.

Figure 18.11 Apicomplexans. (a) A gametocyte of *Plasmodium falciparum* in a blood smear. The gametocyte is the stage in the malarial parasite life cycle that infects the mosquito vector. (b) Sporozoites of *Toxoplasma gondii*.

Apicomplexans

Apicomplexans are nonphototrophic obligate parasites that cause severe human diseases such as malaria (*Plasmodium* species, **Figure 18.11a**), toxoplasmosis (*Toxoplasma*, **Figure 18.11b**), and coccidiosis (*Eimeria*). These organisms are characterized by nonmotile adult stages, and nutrients are taken up in soluble form across the cytoplasmic membrane as in bacteria and fungi.

Apicomplexans produce structures called *sporozoites* (**Figure 18.11b**; ▶ Section 34.5 and **Figure 34.12**), which function in transmission of the parasite to a new host, and the name apicomplexan derives from the presence at one apex of the sporozoite of a complex of organelles that penetrate host cells. Apicomplexans also contain *apicoplasts*. These are degenerate chloroplasts that lack pigments and photosynthetic capacity but contain a few of their own genes. Apicoplasts catalyze fatty acid, isoprenoid, and heme biosyntheses, and export their products to the cytoplasm. It is hypothesized that apicoplasts are derived from red algal cells engulfed by apicomplexans in a secondary endosymbiosis (**Figures 18.2 and 18.3**). Over time, the chloroplast of the red algal cell degenerated to play a nonphototrophic role in the apicomplexan cell.

Both vertebrates and invertebrates can be hosts for apicomplexans. In some cases, an alternation of hosts takes place, with some stages of the life cycle linked to one host and some to another. Important apicomplexans are the coccidia, which are typically parasites of birds, and species of *Plasmodium*, which are malarial parasites (**Figure 18.11a**). We reserve detailed discussion of malaria—a disease that has killed more humans than any other disease—for Section 34.5.

Check Your Understanding

- How does the organism *Paramecium* move?
- What health problem is associated with the organism *Gonyaulax*?
- What are apicoplasts, which organisms have them, and what are their functions?

18.5 Stramenopiles

KEY GENERA: *Phytophthora*, *Nitzschia*, *Ochromonas*, *Macrocystis*

The *Stramenopiles* include both chemoorganotrophic and phototrophic microorganisms as well as macroorganisms. Members of this group bear flagella with many short, hairlike extensions (**Figure 18.2**), and this morphological feature gives the group its name (from Latin *stramen* for “straw” and *pilus* for “hair”). The diatoms, oomycetes, golden algae, and brown algae are the major groups of *Stramenopiles* (**Figure 18.3**).

Diatoms

Diatoms include over 200 genera of unicellular, phototrophic, microbial eukaryotes, and are major components of the planktonic (suspended) phytoplankton microbial community in marine and freshwaters. Diatoms characteristically produce an exoskeleton made of silica to which protein and polysaccharide are added. The exoskeleton, which protects the cell against predation, exhibits widely different shapes in different species and can be highly ornate (**Figure 18.12**). This external structure, called a *frustule*, often remains after the cell dies and the organic materials have disappeared. Diatom frustules typically show morphological symmetry, including *pinnate symmetry* (having similar parts arranged on opposite sides of an axis, as in the common diatom *Nitzschia*, **Figure 18.12b**), and *radial symmetry*, as in the marine diatoms *Thalassiosira* and *Asterolampra* (**Figure 18.12c, d**). Because the diatom frustules, which are composed mainly of silica, are resistant to decay, these structures can remain intact for long periods and often sink and remain in the sediments for millions of years. Diatom frustules constitute some of the best-known unicellular eukaryotic fossils, and from dating of frustule samples, it has been shown that diatoms first appeared on Earth relatively recently, about 200 million years ago.

Oomycetes

The oomycetes, also called *water molds*, were previously grouped with fungi based on their filamentous growth and the presence of **coenocytic** (that is, multinucleate) hyphae, morphological traits characteristic of fungi (**Section 18.9**). Phylogenetically, however, the oomycetes are distant from fungi and are closely related to other *Stramenopiles* (**Figure 18.3**). Oomycetes differ from fungi in other fundamental ways, as well. For example, the cell walls of oomycetes are typically made of cellulose instead of the chitin cell walls of fungi, and the water molds have flagellated cells, which are lacking in all but a few fungi. Nonetheless, oomycetes are ecologically similar to fungi in that they grow as a mass of hyphae decomposing dead plant and animal material in aquatic habitats.

Oomycetes have had a major impact on human society, as many species are plant pathogens (phytopathogens). The oomycete *Phytophthora infestans*, which causes late blight disease of potatoes, contributed to massive famines in Ireland in the mid-nineteenth century. The famines led to the death of a million Irish and triggered great waves of Irish immigration to North America. Other major phytopathogens include *Pythium*, a common pathogen of greenhouse seedlings, and *Albugo*, which causes “white rusts” on several agricultural crops.

(b–d) Scanning electron micrographs of diatom frustules showing pinnate (part b) or radial (parts c, d) symmetry. Diatoms vary considerably in size from very small species about 5 μm wide to larger species up to 200 μm wide.

Golden Algae and Brown Algae

Along with the diatoms, golden and brown algae form major lineages of *Stramenopiles*. Golden algae, also called *chrysophytes*, are primarily unicellular marine and freshwater phototrophs. Some species are chemoorganotrophs and feed either by phagocytosis or by transporting soluble organic compounds across the cytoplasmic membrane. Some golden algae, such as *Dinobryon* (Figure 18.13a), found in freshwater, are colonial. However, most golden algae are unicellular and motile by the activity of two flagella of unequal length.

Golden algae are so named because of their golden-brown color (Figure 18.13a, c). This is due to chloroplast pigments dominated by the brown-colored carotenoid fucoxanthin. The major chlorophyll pigment in golden algae is chlorophyll *c* rather than chlorophyll *a*, and they lack the phycobiliproteins present in red algal

chloroplasts (Section 18.15). Cells of the unicellular golden alga *Ochromonas*, the best-studied genus of this group, have only one or two chloroplasts (Figure 18.13c).

Brown algae are primarily marine and are multicellular and typically macroscopic. No unicellular brown algae are known. The kelps, such as the giant kelp *Macrocystis* (Figure 18.13b), which can grow up to 50 m in length, are perhaps the most widespread of brown algae. *Fucus*, another common seaweed of intertidal regions, can grow up to 2 m. As their name implies, brown algae are brown or green-brown in color depending on how much of the carotenoid pigment fucoxanthin they produce. Most marine “seaweeds” are brown algae and their rapid growth, especially in cold marine waters, can cause nuisance odor problems when they wash ashore and decay.

Figure 18.13 Golden and brown algae. (a) *Dinobryon*, a golden alga (family *Chrysophyceae*) that forms branched colonies. (b) *Macrocystis*, a marine kelp belonging to the brown algae (family *Phaeophyceae*). (c) *Ochromonas*, a unicellular chrysophyte. The golden or brown color of the chloroplasts of these algae is due to the pigment fucoxanthin.

Check Your Understanding

- What structure of diatoms accounts for their excellent fossil record?
- In what ways do oomycetes differ from and resemble fungi?
- Which chlorophyll pigment is found in golden and brown algae?

18.6 Rhizaria

Rhizaria form a diverse group of protists that includes the chlorarachniophytes, radiolarians, and foraminiferans (Figure 18.3). They are distinguished from other protists by their threadlike cytoplasmic extrusions (pseudopodia) by which they move and feed. Some *Rhizaria* have amoeboid morphology and were once mistakenly classified as amoebae because of this and their pseudopodia, but it is now known that many phylogenetically diverse organisms employ pseudopodia for motility and feeding purposes.

Chlorarachniophytes

Chlorarachniophytes are freshwater and marine amoeba-like phototrophs that develop a flagellum for dispersal. The group's acquisition of green algal chloroplasts is a prime example of a secondary endosymbiosis (Figure 18.2) and shows how extensively this process has molded several phylogenetically distinct lineages of microbial eukaryotes (Figure 18.3).

Chloroplasts typically have two membranes (◀ Section 2.14; Figures 2.46 and 14.9), derived from the inner and outer membranes of *Cyanobacteria*, which have a gram-negative cell envelope (◀ Sections 2.3 and 2.4). Chloroplasts in chlorarachniophytes, however, have four membranes. In addition, they have **nucleomorphs** tucked in between the two sets of chloroplast membranes. Nucleomorphs are remnant nuclei left over from when the algal endosymbionts were acquired during secondary endosymbiosis (Section 18.1). Both the nucleomorphs and the extra membranes were derived from this algal endosymbiont (Figure 18.2).

It is a testament to endosymbiosis to consider that chlorarachniophytes have merged a minimum of five different genomes: the host genome, the host mitochondrial genome, the algal endosymbiont

genome (which has become the nucleomorph), the algal endosymbiont mitochondrial genome, and the algal endosymbiont chloroplast genome! Most nonessential or duplicate genes have been deleted over time, and many genes from the mitochondria and chloroplasts have been transferred to the host genome. As a result, the majority of genes in a chlorarachniophyte are present in the nucleus of the host cell. The nucleomorph itself is greatly reduced in size relative to its ancestor and over time may be lost completely from the chloroplast.

Foraminiferans

In contrast to chlorarachniophytes, foraminiferans are exclusively marine microbes and form shell-like structures called *tests*, which have distinctive characteristics and are often quite ornate (Figure 18.14a). Tests are typically made of organic materials reinforced with calcium carbonate. The test is not firmly attached to the cell, and the amoeba-like cell may extend partway out of the test during feeding. However, because of the weight of the test, the cell usually sinks to the bottom of the water column, and it is thought that the organisms feed on dissolved organic matter and particulate deposits, primarily bacteria, other protists, and the remains of dead organisms near the sediments. Foraminiferan cells can also host a variety of algae that form

Figure 18.14 Foraminifera and radiolaria. (a) A foraminiferan. Note the ornate and multilobed test. The test is about 1 mm wide. (b) A spiked radiolarian of the *Nassellaria* group. A test is about 150 μm wide. Both a and b are colorized scanning electron micrographs.

endosymbiotic relationships with the protist and supply it with organic carbon, probably in exchange for inorganic nutrients derived from the breakdown of dead organisms. Phototrophs are found primarily in planktonic foraminifera that remain suspended in the water column to provide their endosymbionts with sufficient sunlight.

Foraminiferan tests (Figure 18.14a) are relatively resistant to decay and are readily fossilized. These buried and preserved tests are quite useful to geologists. Because particular taxa of foraminifera are typically associated with particular strata in the geological record, fossilized foraminiferan tests in samples obtained from exploratory wells are used by oil industry paleontologists as a means to date and assess the petroleum potential of a given drill site.

Radiolarians

Radiolarians are chemoorganotrophic and mostly planktonic marine eukaryotes that reside in the upper 100 m of the ocean where they consume bacteria and particulate organic matter. Some species associate with algae that take on a symbiotic (but not endosymbiotic) role and supply nutrients to the radiolarian.

The name “radiolarian” comes from the radial symmetry of their tests, transparent or translucent mineral skeletons made of silica in one fused piece (Figure 18.14b). Along with the accumulation of lipid droplets and large cytoplasmic vacuoles, the needle-like pseudopodia of radiolarians probably help keep the organisms from sinking in their mainly open ocean (planktonic) habitats. However, when cells eventually die, their tests settle to the ocean floor and can build up over time into thick layers of slowly decaying cell material.

18.7 Haptophytes

KEY GENUS: *Emiliania*

Haptophytes are a group of unicellular and free-living phototrophic protists found in aquatic environments. Members of this group are widespread and abundant in the oceans, where they have a major impact on the biosphere. All haptophytes share several structural features including the presence of two flagella, two chloroplasts (derived from secondary endosymbiosis of red algae, Figures 18.2 and 18.3), and a unique structure called a *haptonema*. While all haptophytes are phototrophic, some are mixotrophic, obtaining energy both from photosynthesis and from the ingestion of smaller organisms or detritus. The haptonema, for which the group is named, is used when feeding, but it can also facilitate attachment and the avoidance of predators.

Coccolithophores

Haptophytes, at some point in their life cycle, typically possess rigid polysaccharide plates on their outer surface. The morphology of these plates can vary dramatically between species. One major group

of haptophytes, the *coccolithophores*, are distinguished by their ability to form intricate mineralized plates made of calcite, a form of calcium carbonate.

Coccolithophores (Figure 18.15) are one of the most abundant and widely distributed unicellular phototrophic eukaryotes in the oceans. One of the most widespread and well characterized of the coccolithophores is *Emiliania huxleyi*. Coccolithophores are found in the photic zone of the ocean from tropical to subpolar latitudes. They can contribute 1 to 10% of the primary productivity in these systems under normal conditions, but they can also form massive blooms in which they account for more than 40% of photosynthetic activity. These blooms can span hundreds of thousands of square kilometers and are visible from space (see MicrobiologyNow in the chapter opener).

Coccolithophores have an exoskeleton composed of *coccoliths*, which are plates made from calcium carbonate (Figure 18.15). The plates could have several purposes. For example, they might be used to enhance photosynthesis by attenuating or focusing sunlight into the cell. Alternatively, the plates may protect the cell from grazing or from attack by bacteria or viruses.

Whatever their purpose, the production of coccolithophore plates has a major impact on Earth's carbon cycle and, by extension, its climate. This is because the plates make coccoliths heavy, and the cells

Dr. Jeremy R. Young

These phototrophic microbes have an exoskeleton composed of interlocking coccoliths made from calcium carbonate. *Emiliania huxleyi*, center top, is about 10 μm in diameter.

eventually sink, exporting carbon to the seafloor in the form of calcite. In this way, coccolithophores are a “biological pump” that removes CO₂ from the atmosphere and deposits it on the seafloor where it will eventually form sedimentary rocks (► Section 21.7 and Figure 21.20c). Indeed, coccoliths are a main component of the chalk deposits found in many regions of the world such as those of the famous White Cliffs of Dover in England. These deposits represent millions of years of carbon deposited on the seafloor, and they are a dramatic illustration of the power of microbes to influence the biosphere.

Life Cycle

Haptophytes have a life cycle that alternates between haploid and diploid cells; only haploid cells contain a haptonema. In the case of *E. huxleyi* (Figure 18.15; ► Figure 21.20a), diploid cells are observed most commonly and are responsible for the formation of blooms. Diploid cells are nonmotile, reproduce by binary fission to form diploid progeny, and form structurally complex exoskeletons composed of interlocking coccolith scales (Figure 18.15). In response to an environmental trigger, the nature of which remains poorly characterized, diploid cells undergo meiosis resulting in haploid progeny. The haploid cells are motile and do not form interlocking calcified exoskeletons. These noncalcified haploid cells divide by binary fission until some environmental trigger causes them to fuse with another haploid cell, returning the organism to the diploid state.

The two life stages of the coccolithophores are thus so morphologically different that they can easily be mistaken for different species. In nature, however, it is likely that the exoskeleton-containing (diploid) form predominates because this is the form seen in the massive blooms of coccolithophores in oceans worldwide.

- In what way do coccolithophores influence the global climate?

18.8 Amoebozoa

KEY GENERA: *Amoeba*, *Entamoeba*, *Physarum*, *Dictyostelium*

The Amoebozoa are a large group of terrestrial and aquatic protists that use lobe-shaped pseudopodia for movement and feeding, in contrast to the threadlike pseudopodia of rhizaria. The major groups of Amoebozoa are the gymnamoebas, the entamoebas, and the plasmodial and cellular slime molds. Phylogenetically, the Amoebozoa diverged from a lineage that eventually led to the fungi and animals (Figure 18.3).

Gymnamoebas and Entamoebas

The gymnamoebas are free-living protists that inhabit aquatic and soil environments. They use pseudopodia to move by a process called *amoeboid movement* (Figure 18.16) and feed by phagocytosis on bacteria, other protists, and particulate organic materials. Amoeboid movement results from streaming of the cytoplasm as it flows forward at the less contracted and viscous cell tip, taking the path of least resistance. Cytoplasmic streaming is facilitated by microfilaments (◄ Section 2.15), which exist in a thin layer just beneath the

Figure 18.16 Time-lapse view of the amoebozoan *Amoeba proteus*. The time interval from top to bottom is about 6 sec. The arrows point to a fixed spot on the surface. A single cell is about 80 μm wide.

cytoplasmic membrane. *Amoeba* (Figure 18.16) is a common organism in pond waters, with species varying in size from 15 μm in diameter (clearly microscopic) to over 750 μm (visible with the naked eye).

In contrast to gymnamoebas, the entamoebas are parasites of vertebrates and invertebrates. Their usual habitat is the oral cavity or intestinal tract of animals. The anaerobe *Entamoeba histolytica* is pathogenic in humans and causes amebic dysentery, an ulceration of the intestinal tract that results in bloody diarrhea. This parasite forms cysts that are transmitted from person to person by fecal contamination of water, food, and eating utensils. In Section 34.00 we discuss the etiology and pathogenesis of amebic dysentery, an important cause of death from intestinal parasites in humans.

Slime Molds

The **slime molds** were previously grouped with fungi since they undergo similar life cycles and produce fruiting bodies with spores for dispersal. As protists, however, slime molds are motile and can move across a solid surface fairly quickly (see Figures 18.17–18.19). Slime molds are divided into two groups: *plasmodial slime molds* (also called *acellular slime molds*), whose vegetative forms are masses of protoplasm of indefinite size and shape called *plasmodia* (Figure 18.17), and *cellular slime molds*, whose vegetative forms are single amoebae. Slime molds live primarily on decaying plant matter, such as leaf litter, logs, and soil, where they consume other microorganisms, especially bacteria. Slime molds can maintain themselves in a vegetative state for long periods but eventually form differentiated spore-like structures that can remain dormant and then germinate later to once again generate the active amoeboid state.

Plasmodial slime molds, such as *Physarum*, exist in the vegetative phase as an expanding single mass of protoplasm called the *plasmodium* that contains many diploid nuclei (Figure 18.17). The plasmodium is actively motile by amoeboid movement, and from this phase, a sporangium containing haploid spores can be produced. When conditions are favorable the spores germinate to yield haploid flagellated swarm cells. The fusion of two swarm cells then regenerates a diploid plasmodium.

Figure 18.17 Slime mold. The plasmodial slime mold *Physarum* growing on an agar surface. The plasmodium is about 5 cm long and 3.5 cm wide.

In contrast to their plasmodial relatives, cellular slime molds are individual haploid cells and form diploids only under certain conditions. The well-studied cellular slime mold *Dictyostelium discoideum* undergoes an asexual life cycle in which vegetative cells aggregate, migrate as a cell mass, and eventually produce fruiting bodies in which cells differentiate and form spores (Figures 18.18 and 18.19). When cells of *Dictyostelium* are starved, they aggregate and form a pseudoplasmodium; in this stage cells lose their individuality, but do

not fuse. Aggregation is triggered by the production of cyclic adenosine monophosphate (cAMP). The first cells of *Dictyostelium* that produce this compound attract neighboring cells and eventually aggregate into motile masses of cells called *slugs*. Fruiting body formation begins when the slug becomes stationary and vertically oriented. The emerging structure differentiates into a stalk and a head. The stalk cells form cellulose, which provides the rigidity of the stalk, and the head cells differentiate into spores. Eventually, spores are released and dispersed, with each spore forming a new amoeba (Figures 18.18 and 18.19).

In addition to this asexual process, *Dictyostelium* can produce sexual spores. These form when two amoebae in an aggregate fuse to form a single giant amoeba. A thick cellulose wall develops around this cell to form a structure called the *macrocyt*, and this can remain dormant for long periods. Eventually, the diploid nucleus undergoes meiosis to form haploid nuclei that become integrated into new amoebae that can once again initiate the asexual cycle.

In Part III, we consider the fungi, a huge group of microbial eukaryotes whose service to the ecosystem by decomposing dead organic material cannot be understated.

III • Fungi

Fungi are nonphototrophic eukaryotic microbes that form rigid cell walls made of chitin. Fungi are major agents of decomposition in soil and other habitats, and some form symbiotic relationships with plants.

The *Fungi* are a large, diverse, and widespread group of mostly nonmotile organisms that includes such well-known groups as the *molds*, *mushrooms*, and *yeasts*. Approximately 100,000 fungal species have been described, and as many as 1.5 million species could exist. Fungi form a phylogenetic cluster distinct from protists and are the microbial group most closely related to animals (Figure 18.3).

Most fungal species are microscopic and terrestrial. They inhabit soil or dead plant matter and play crucial roles in the decomposition of organic matter. A large number of fungal species are plant pathogens, and a few cause diseases of animals, including humans (Chapter 34). Certain species of fungi also establish symbiotic associations with plants, facilitating the plant's acquisition of minerals from soil, and many fungi benefit humans through fermentation and the synthesis of antibiotics.

18.9 Fungal Physiology, Structure, and Symbioses

In this section we describe some general features of fungi, including their physiology, cell structure, and the symbiotic associations they develop with plants and animals. In the following section, we examine fungal reproduction and phylogeny.

Nutrition, Physiology, and Ecology

Fungi are chemoorganotrophs—typically displaying simple nutritional requirements—and most are aerobic. Fungi nourish themselves by secreting extracellular enzymes that digest polymeric

materials, such as polysaccharides or proteins, into monomers that are assimilated as sources of carbon and energy. As decomposers, fungi digest dead animal and plant materials. As parasites of plants or animals, fungi use the same mode of nutrition but take up nutrients from the living cells of the plants and animals they invade rather than from dead organic materials.

A major ecological activity of fungi, especially the basidiomycetes, is the decomposition of wood, paper, cloth, and other products derived from these natural sources. Lignin, a complex polymer in which the building blocks are phenolic compounds, is an important constituent of woody plants, and in association with cellulose, it confers rigidity on them. Lignin is decomposed in nature almost exclusively through the activities of certain basidiomycetes called *wood-rotting fungi*. Two types of wood rot are known: *brown rot*, in which the cellulose is attacked preferentially while the lignin is left unmetabolized, and *white rot*, in which both cellulose and lignin are decomposed. The white rot fungi are of major ecological importance because they play such a key role in decomposing woody materials in forests.

Fungal Morphology, Spores, and Cell Walls

Most fungi are multicellular, forming a network of filaments called *hyphae* (singular, *hypha*) from which asexual spores are produced (Figure 18.20). Hyphae are tubular cell walls that surround the cytoplasmic membrane. Fungal hyphae are often septate, with cross-walls dividing each hypha into separate cells. In some cases, however, the vegetative cell of a fungal hypha contains more than one nucleus, and hundreds of nuclei can form as a result of repeated nuclear divisions without the formation of cross-walls, a condition called *coenocytic*. Each hyphal filament grows mainly at the tip by extension of the terminal cell (Figure 18.20).

Hyphae typically grow together across and above a surface to form a compact, macroscopically visible tuft called a *mycelium* (Figure 18.21a). From the mycelium, aerial hyphae reach up into the air above the surface, and spores called **conidia** are formed on their tips (Figure 18.21b). Conidia are asexual spores and they are often pigmented black, green, red, yellow, or brown (Figure 18.21). Conidia give the mycelium a dusty appearance (Figure 18.21a) and function to disperse the fungus to new habitats. Some fungi form macroscopic reproductive structures called *fruiting bodies* (**mushrooms** or puffballs, for example), in which millions of spores are produced that can be dispersed by wind, water, or animals (Figure 18.22). In contrast to mycelial fungi, some fungi grow as single cells; these are the **yeasts**.

Most fungal cell walls consist of **chitin**, a polymer of *N*-acetylglucosamine. Chitin is arranged in the walls in microfibrillar bundles, as is cellulose in plant cell walls, to form a thick, tough wall structure. Other polysaccharides such as mannans and galactosans, or even cellulose itself, replace or supplement chitin in some fungal cell walls. Fungal cell walls are typically 80–90% polysaccharide, with only small amounts of proteins, lipids, polyphosphates, and inorganic ions making up the wall-cementing matrix.

Note the masses of filamentous cells (mycelia) and asexual spores that give the colonies a dusty, matted appearance. (b) Conidiophore and conidia of *Aspergillus fumigatus* (see Figure 18.20b). The conidiophore is about 300 μm long and the conidia here are about 3 μm wide. These cells were stained to improve contrast. Besides being a common saprophyte, *Aspergillus* can be pathogenic, causing serious pulmonary and occasional systemic infections in humans and some domestic animals. Cancer patients and others with weakened immune systems are particularly susceptible to aspergillosis.

Symbioses and Pathogenesis

Most plants are dependent on certain fungi to facilitate their uptake of minerals from soil. These fungi form symbiotic associations with the plant roots called *mycorrhizae* (the word means, literally, “fungus roots”). Mycorrhizal fungi establish close physical contact with the roots and help the plant obtain phosphate, as well as other minerals, and water from the soil. In return, the fungi obtain nutrients such as sugars from the plant root (► Figure 23.22). There are two kinds of mycorrhizal associations. One, *ectomycorrhizae*, typically forms between basidiomycetes (Section 18.14) and the roots of

Figure 18.22 Mushroom life cycle. Mushrooms typically develop underground and then emerge on the surface rather suddenly (usually overnight), triggered by an influx of moisture. Photos of stages in formation of a common lawn mushroom (see also Section 18.14).

woody plants, while the second, *endomycorrhizae*, forms between glomeromycete fungi (Section 18.12) and many nonwoody plants. Some fungi also form associations with cyanobacteria or green algae. These are the *lichens*, the colorful and crusty growths often seen on the surfaces of trees and rocks. We explore the biology of lichens and mycorrhizae in more detail in Sections 23.1 and 23.5, respectively.

Fungi can invade and cause disease in plants and animals. Fungal plant pathogens cause widespread crop and plant damage worldwide, and fruit and grain crops in particular suffer significant yearly losses as a result of fungal infection. Human fungal diseases, called *mycoses*, range from relatively minor and easily cured conditions, such as athlete's foot and jock itch, to serious, life-threatening systemic mycoses, such as histoplasmosis. We consider some major fungal diseases of humans in Chapter 34.

Check Your Understanding

- What are conidia? How does a conidium differ from a hypha? From a mycelium?
- What is chitin and where is it present in fungi?
- Distinguish between mycorrhizae and lichens.

18.10 Fungal Reproduction and Phylogeny

Fungi reproduce by *asexual* means in one of three ways: (1) by the growth and spread of hyphal filaments; (2) by the asexual production of spores (conidia; Figures 18.20 and 18.21); or (3) by simple cell division, as in budding yeasts (Figure 18.23). Most fungi also form sexual spores, typically as part of an elaborate life cycle. Some fungi, such as the well-known mold *Penicillium* (the source of the antibiotic penicillin), were long thought to lack a sexual stage and reproduce only by way of conidia. But it has now been shown that the life cycle of *Penicillium* includes a sexual stage.

Sexual Spores of Fungi

Some fungi produce spores as a result of sexual reproduction. The spores develop from the fusion of either unicellular gametes or specialized hyphae called *gametangia*. Alternatively, sexual spores can originate from the fusion of two haploid cells to yield a diploid cell; this then undergoes meiosis and mitosis to yield individual haploid spores.

Depending on the group, different types of sexual spores are produced. Spores formed within an enclosed sac (ascus) are called *ascospores*. Many yeasts produce ascospores, and we consider sporulation in the common baker's yeast *Saccharomyces cerevisiae* in Section 18.13. Sexual spores produced on the ends of a club-shaped structure (basidium) are *basidiospores* (Figure 18.22 and see Figure 18.31c). *Zygospores*, produced by zygomycetous fungi such as the common bread mold *Rhizopus* (Section 18.12), are macroscopically visible structures that result from the fusion of hyphae and genetic exchange. Eventually the zygospore matures and produces asexual spores that are dispersed by air and germinate to form new fungal mycelia. Chytrid fungi produce sexual spores, motile by eukaryotic flagella, called *zoospores*.

Figure 18.23 The common baker's and brewer's yeast *Saccharomyces cerevisiae* (*Ascomycota*). In this colorized scanning electron micrograph, note the budding division and scars from previous buds. A single cell is about 6 μm in diameter.

Sexual spores of fungi are typically resistant to drying, heating, freezing, and some chemical agents. However, neither sexual nor asexual spores of fungi are as resistant to heat as bacterial endospores (◀ Section 2.8). Both asexual and sexual spores of fungi can germinate and develop into a new hypha.

The Phylogeny of Fungi

Fungi share an ancestor with animals and are more closely related to animals than any other eukaryotic group (Figure 18.3). The last common ancestor of all fungi likely existed sometime between 450 million and 1.5 billion years ago. One of the earliest fungal lineages is thought to be the *Chytridiomycota*, an unusual group of motile fungi that produce zoospores. Thus, the lack of flagella in most fungi indicates that motility is a characteristic that has been lost at various times in different fungal lineages.

Some of the major groups of fungi are shown in the evolutionary tree in Figure 18.24. The phylogeny shown in this figure includes several distinct fungal groups: the *Microsporidia*, *Chytridiomycota*, *Mucoromycota*, *Glomeromycota*, *Ascomycota*, and *Basidiomycota* (these groups are considered in detail in the next four sections). The vast majority of described fungal species belong to the *Ascomycota* and *Basidiomycota*. The *Ascomycota* are a large and diverse group of fungi that includes yeasts, such as *Saccharomyces* (Figures 18.23 and 18.24), and molds, such as *Aspergillus* (Figure 18.21). The *Basidiomycota* include fungi that form mushrooms (Figures 18.22, 18.24, and see Figure 18.31), as well as many important plant pathogens such as the rusts and smuts. While a tremendous diversity of fungal species have already been cultured and described, phylogenetic analyses of fungal DNA sequences recovered from environmental samples (▶ Sections 19.6 and 19.8) indicate that more than 90% of fungal species remain uncultured. Clearly, we have much to learn about the biology and phylogeny of the fungi.

Check Your Understanding

- Why is the mold *Penicillium* economically important?
- What are the major differences between ascospores and conidia?
- To what major group of macroorganisms are fungi most closely related?

Figure 18.24 Phylogeny of fungi. This phylogenetic tree depicts the relationships among the major groups (phyla) of fungi. A typical genus is listed for each group and depicted in the tree.

18.11 Microsporidia and Chytridiomycota

KEY GENERA: *Allomyces*, *Batrachochytrium*, *Encephalitozoon*

The *Microsporidia* and *Chytridiomycota* are ancient phylogenetic groups of parasitic or saprophytic fungi (Figure 18.24). Microsporidia are obligate parasites of a wide variety of animal hosts including humans, whereas the *Chytridiomycota* are primarily aquatic fungi whose species are either parasites or saprophytes.

Microsporidia

Microsporidia are tiny (2–5 μm) unicellular parasites of animals and protists. Based on 18S ribosomal RNA gene sequencing and their lack of mitochondria, *Microsporidia* were once thought to form a very early-branching lineage of *Eukarya*. However, composite gene

and protein sequencing has shown the microsporidians are fungi closely related to the *Chytridiomycota* (Figure 18.24). There remains debate as to whether the *Microsporidia* should be included as one of the most deeply divergent lineages within the fungi or whether they should instead be classified as a distinct lineage closely related to fungi.

Microsporidia have adapted to a parasitic lifestyle. They exist as spores when outside of the host. When near a host cell they extend a helical polar tubule that penetrates the host cytoplasmic membrane. The spore then injects its *sporoplasm* into the host cell. The sporoplasm replicates within the cytoplasm of the host cell, forming new spores as it completes its life cycle. Eventually, the cell membrane of the host is disrupted and the spores are released into the surrounding environment, free to infect new cells.

Like most obligate parasites, microsporidia have undergone significant genome reduction, losing many features that would allow them to live outside of a host cell. The microsporidium *Encephalitozoon* (Figure 18.24 and Figure 18.25a), for example, lacks not only mitochondria but also a Golgi complex (another key eukaryotic cell structure, Section 2.15 and Figure 2.42). Moreover, *Encephalitozoon* cells contain a very small genome of only 2.9 Mbp and only about 2000 genes (this is 1.5 Mbp and 2600 genes smaller than that of the bacterium *Escherichia coli*). The *Encephalitozoon* genome lacks genes for major metabolic pathways, such as the citric acid cycle (Section 3.6), meaning that this pathogen must depend on its host for even the most basic of metabolites and metabolic processes.

In humans, *Encephalitozoon* causes chronic debilitating diseases of the intestine, lung, eye, muscle, and some internal organs but is uncommon among healthy adults with normal immune systems. However, microsporidial diseases have appeared with increasing frequency in immune-compromised individuals, such as those with HIV/AIDS or those on long-term administration of immune-suppressing drugs, such as those who have had organ transplants.

Chytridiomycota

Chytridiomycota, or *chytrids*, are one of the earliest diverging lineage of fungi (Figure 18.24), and their name refers to the structure of the fruiting body, which contains their *zoospores* (Section 18.10). These spores are unusual among fungal spores in being flagellated and motile and are ideal for dispersal of these organisms in the aquatic environments, mostly freshwater and moist soils, where they are commonly found.

Many species of chytrids are known and some exist as single cells, whereas others form colonies with hyphae. They include both free-living forms that degrade organic material, such as *Allomyces*, and parasites of animals, plants, and protists. The chytrid *Batrachochytrium dendrobatidis* causes chytridiomycosis of frogs (Figure 18.25b), a condition in which the organism infects the frog's epidermal layers, leading to a loss of ions across the membrane and osmotic imbalance. Chytrids have been implicated in the massive die-off of frogs and some other amphibians worldwide, probably in response to increases in global temperatures that have stimulated chytrid proliferation and to increased animal susceptibility due to habitat loss and aquatic pollution.

Figure 18.25 Microsporidia and Chytridiomycota. (a) Colorized transmission electron micrograph of thin sections of cells of the microsporidium *Encephalitozoon intestinalis* (arrows) growing in human intestinal cells. (b) Cells of the chytrid *Batrachochytrium dendrobatidis* stained pink growing on the surface of frog epidermis.

Unresolved aspects of the phylogeny of chytrids suggest that this group is not monophyletic. That is, some organisms currently classified as chytrids may actually be more closely related to species of other fungal groups, such as the *Mucoromycota*, to which we turn next. As is true for the protists, much about the evolution of the chytrids and other groups of fungi remains to be learned.

Check Your Understanding

- What animal group has been most affected by chytrids?
- What are some features of *Microsporidia* that distinguish them from chytrids?

18.12 Mucoromycota and Glomeromycota

KEY GENERA: *Rhizopus*, *Glomus*

We consider two groups of fungi here, the *Mucoromycota*, known primarily for their role in food spoilage, and the *Glomeromycota*, important fungi in certain mycorrhizal associations. *Mucoromycota* are commonly found in soil and on decaying plant material, whereas *Glomeromycota* form symbiotic relationships with plant roots. All of these fungi are coenocytic (multinucleate), and while *Glomeromycota* have an exclusively asexual life cycle, *Mucoromycota* often have a life cycle that includes sexual spores called *zygospores* (Section 18.10).

Mucoromycota

The common black bread mold *Rhizopus nigricans* (Figure 18.26) is a widespread zygomycete (zygomycetes are fungi that produce zygospores). This organism undergoes a complex life cycle that includes both asexual and sexual reproduction. In the asexual phase the mycelia form sporangia within which haploid spores are produced. Once released, these haploid spores disperse and eventually germinate, giving rise to vegetative mycelia. In the sexual phase, mycelial gametangia of different mating types (analogous to male and female, see Section 18.13) fuse to yield a cell with two nuclei. This

diploid cell eventually develops into a *zygospore*, which can remain dormant and resist dryness and other unfavorable conditions. When conditions are favorable, the zygospore can germinate, forming either a diploid mycelium or a sporangium that produces haploid spores for dispersal.

Most species of *Rhizopus* and related zygomycetes are harmless saprophytes whose airborne spores land and form spreading colonies on stale bread (Figure 18.26a) and various moist surfaces in the home or on walls and crevices in buildings where moisture is trapped. However, some species are human pathogens. If inhaled in sufficient amounts, spores of pathogenic *Rhizopus* species can cause serious infections of the lungs, sinuses, eyes, nose, and mouth leading to swelling of facial features, asthma-like symptoms, and even fatal systemic fungal infections if the initial infection is not promptly treated.

Glomeromycota

The *Glomeromycota* are a relatively small and unique group of obligately symbiotic fungi in which all known species form associations with plants called *endomycorrhizae* (Section 18.9). As many as 80% or more of land plant species form these associations in which the fungal hyphae enter the plant cell and aid the plant's acquisition of phosphate from the soil in return for fixed carbon from the plant. Most of these *Glomeromycota* are *arbuscular mycorrhizae*, fungi that form structures called *arbuscules* that penetrate cells of their plant host and specialize in nutrient exchange (► Section 23.5). As plant symbionts, glomeromycetes are thought to have played a pivotal role in the ability of early vascular plants to colonize land.

As far as is known, glomeromycetes reproduce only asexually and are mostly coenocytic in their hyphal morphology. Asexual spores of *Glomus* (Figure 18.24), a major genus of endomycorrhizae, are collected from the roots of cultivated plants and used as an agricultural inoculant to promote vigorous symbiotic associations between plant and fungus. This natural approach to plant fertilization is a widespread practice in small, sustainable farming operations and has been shown to increase both the growth and nutrient content of tomato, pepper, squash, bean, and several other small fruit and vegetable plants.

Figure 18.26 Mucoromycota. (a) Moldy bread from growth of the zygomycete *Rhizopus nigricans*. (b) Stained mycelium of *Rhizopus* showing the black aerial sporangia containing asexual spores.

Check Your Understanding

- Contrast the habitats of *Mucoromycota* and *Glomeromycota*.
- How does the fungus *Glomus* aid the acquisition of nutrients by plants?

18.13 Ascomycota

KEY GENERA: *Saccharomyces*, *Candida*, *Aspergillus*

The *Ascomycota*, also called the ascomycetes, are the largest and most diverse group of fungi and they range from single-celled species, such as the baker's yeast *Saccharomyces* (Figure 18.27 and Figure 18.23), to species that grow as filaments, such as the common mold *Aspergillus* (Figure 18.21). Ascomycetes are found in aquatic and terrestrial environments and take their name from the production of *asci* (singular, *ascus*), cells in which two haploid nuclei from different mating types fuse to form a diploid nucleus that eventually undergoes meiosis to form haploid ascospores. In addition to ascospores, ascomycetes reproduce asexually by the production of conidia that form at the tips of specialized hyphae called *conidiophores* (Figure 18.21). Both saprophytic and pathogenic yeasts, such as *Candida albicans*, are common in nature. We focus here on the yeast *Saccharomyces* as a model ascomycete.

Saccharomyces cerevisiae

The cells of *Saccharomyces* and other single-celled ascomycetes are spherical, oval, or cylindrical, and cell division typically takes place by budding. In the budding process, a new cell forms as a small outgrowth of the old cell; the bud gradually enlarges and then separates from the parent cell (Figures 18.23 and 18.27).

Yeast cells are typically much larger than bacterial cells and can be distinguished from bacteria microscopically by their larger size and by the obvious presence of internal cell structures, such as the nucleus or cytoplasmic vacuoles (Figure 18.27). Yeasts flourish in sugar-rich habitats such as fruits, flowers, and the bark of trees. Yeasts

Figure 18.27 Growth by budding division in *Saccharomyces cerevisiae*. A time-lapse series of phase-contrast micrographs shows the budding division process starting from a single cell. Note the pronounced nucleus. A single cell of *S. cerevisiae* is about 6 μm in diameter.

are typically facultative aerobes, growing aerobically as well as by fermentation. Several yeasts live symbiotically with animals, especially insects, and a few species are pathogenic for animals including humans (► Section 34.1 and Figure 34.1a,c). The most important commercial yeasts are the baker's and brewer's yeasts, which are species of *Saccharomyces*. The yeast *S. cerevisiae* has been studied as a model eukaryote for many years and was the first eukaryote to have its genome completely sequenced (◀ Section 10.4).

Mating Types and Sexual Reproduction in *Saccharomyces*

The yeast *Saccharomyces* can reproduce by sexual means in which two cells fuse. Within the fused cell, called a *zygote*, meiosis occurs and ascospores are eventually formed. The life cycle of *S. cerevisiae* is depicted in Figure 18.28. *S. cerevisiae* can grow vegetatively (non-sexually) as either haploid or diploid cells. *S. cerevisiae* forms two different types of haploid cells called *mating types* designated α (alpha) and *a* (encoded by genes α and *a*); these are analogous to male and female gametes. The genes α and *a* regulate the production of the peptide hormones α factor and *a* factor, respectively, which are excreted by yeast cells during mating. The hormones bind to cells of the opposite mating type and bring about changes in their cell surfaces that enable the cells to fuse; once mating has

Figure 18.28 Life cycle of a typical ascomycete yeast, *Saccharomyces cerevisiae*. Vegetative growth can occur for long periods as haploid cells or as diploid cells before life cycle events (dashed lines) generate the alternate genetic form.

Figure 18.29 Electron micrographs of mating in the ascomycete yeast *Hansenula wingei*. (a) Two cells have fused at the point of contact. (b) Late stage of mating. The nuclei of the two cells have fused, and a diploid bud has formed at a right angle to the mating cells. This bud becomes the progenitor of a diploid cell line. A cell of *Hansenula* is about 10 μm in diameter.

occurred, the nuclei fuse, forming a diploid zygote (Figure 18.29). The zygote undergoes vegetative growth by budding, but under starvation conditions it undergoes meiosis and generates ascospores (Figure 18.28).

Haploid strains of *S. cerevisiae* are genetically predisposed to be either *a* or α but are able to switch their mating type. This switch occurs when the active mating-type gene is replaced with one of two otherwise “silent” genes, as shown in Figure 18.30. There is a single location on one of the *S. cerevisiae* chromosomes called the *MAT* (for *mating type*) locus, at which either gene *a* or gene α can be inserted. At this locus, the *MAT* promoter controls transcription of whichever gene is present. If gene *a* is at that locus, then the cell is mating-type *a*, whereas if gene α is at that locus, the cell is mating-type α . Elsewhere in the yeast genome are copies of genes *a* and α that are not expressed, and these are the source of the inserted gene. In the switch (Figure 18.30), the appropriate gene, *a* or α , is copied from its silent site and inserted into the *MAT* location, replacing the gene already present. The old mating-type gene is excised and discarded, and the new gene is inserted.

Whichever gene is inserted in the *MAT* locus is the one that will govern the mating type of the strain. It is thus possible for cells from a pure culture of *S. cerevisiae* derived from a single cell to mate, following a mating-type switch in one or more cells in the culture.

Figure 18.30 The cassette mechanism that switches an ascomycete yeast from mating type α to *a*. The cassette inserted at the *MAT* locus determines the mating type. The process shown is reversible, so type *a* can also revert to type α .

- Are ascospores haploid or diploid cells?
- Explain how a *single* haploid cell of *Saccharomyces* can eventually yield a diploid cell.

18.14 Basidiomycota

KEY GENERA: *Agaricus*, *Amanita*

Basidiomycota are a large group of fungi, with over 30,000 species described. Many are the commonly recognized mushrooms and toadstools, some of which are edible, such as the commercially grown mushroom *Agaricus*. Others, such as the mushroom *Amanita* (Figure 18.31a), are highly poisonous. Other basidiomycetes include puffballs, smuts, rusts, and an important human fungal pathogen, *Cryptococcus* (► Sections 34.1 and 34.2 and Figure 34.1a). The defining characteristic of the *Basidiomycota* is the *basidium* (plural, basidia), a structure in which haploid basidiospores are formed by meiosis. The basidium, a word that means “little pedestal” (Figure 18.31c), gives the group its name.

Mushroom Development

During most of its existence, a mushroom fungus lives as a simple haploid mycelium, growing vegetatively in soil, leaf litter, or decaying logs. It is the sexual reproductive phase of basidiomycetes that produces the visible mushroom structure (Figures 18.22 and 18.31). In this process, mycelia of different mating types fuse, and the faster growth of the dikaryotic (two nuclei per cell) mycelium formed from that fusion overgrows and crowds out the parental haploid mycelia. Then, when environmental conditions are favorable, usually following periods of wet and cool weather, the dikaryotic mycelium develops rapidly into the fruiting body.

The mushroom fruiting body, called a *basidiocarp*, begins as a mycelium that differentiates into a small button-shaped structure

Figure 18.31 Mushrooms. (a) *Amanita*, a highly poisonous mushroom. (b) Gills on the underside of the mushroom fruiting body contain the spore-bearing basidia. (c) Light micrograph of basidia and basidiospores from the mushroom *Coprinus*.

underground that then expands into the full-grown basidiocarp that we see aboveground, the mushroom (Figures 18.22 and 18.31a, b). The dikaryotic basidia are borne on the underside of the basidiocarp on flat plates called *gills*, which are attached to the cap of the mushroom (Figure 18.31b, c). The basidia then undergo a fusion of the two nuclei, forming basidia with diploid nuclei. The two rounds of meiotic division generate four haploid nuclei in the basidia, and each of the nuclei becomes a basidiospore. The genetically distinct basidiospores can then be dispersed by wind to new habitats to begin the cycle again, germinating under favorable conditions and growing as haploid mycelia (Figure 18.22).

Pathogenic Basidiomycetes

The smuts and rusts are plant pathogenic basidiomycetes. Smuts are pathogens of cereal grains and other crops, and the genus *Ustilago* contains several species whose hosts include corn, sugarcane, wheat, and several other grains. The fungus targets the reproductive system of the plant, and in corn, smut causes the developing kernels to form massive tumorlike kernels that give the cob a swollen and burned appearance.

Rust fungi attack rapidly growing plant tissues such as emerging shoots, leaves, and fruits. Rust fungi of the genus *Puccinia* can infect any of a wide variety of plants whereas other rust fungi are more host-restricted. Some common rusts include stem rust of wheat and white pine blister rust, a disease of several pine species that can trigger branch dieback and even death of the entire tree. Pine trees weakened by rust fungi are typically more susceptible to insect attack such as from infestations of the pine bark beetle, a highly destructive pest that has destroyed major stands of various pine species in the western United States and central Europe in recent years. Hence, even if the rust fungus itself is not lethal, the damage it does to the overall vigor of the tree can set the stage for lethal attack by a secondary biological agent or even by strong winds.

We now move on to the final part of this chapter where we will explore the world of algae, phototrophic eukaryotes widespread in nature.

Check Your Understanding

- What are some distinguishing features of basidiospores and of zoospores (Section 18.10)?
- Are basidiospores haploid or diploid?

IV • Archaeplastida

The Archaeplastida are a diverse phototrophic lineage that includes plants as well as several groups of algae. Species of red and green algae can be microscopic or macroscopic and are found worldwide, primarily in aquatic habitats.

We conclude our tour of eukaryotic microbial diversity with the kingdom *Archaeplastida*, a large group that includes both red and green algae as well as land plants. As we have previously discussed, only the red and green algae originated from primary endosymbiotic events, whereas other protists containing chloroplasts were the result of secondary endosymbioses (Figures 18.2 and 18.3). Here we focus on the red and green algae, a large and diverse group of eukaryotic organisms that contain chlorophylls and carry out oxygenic photosynthesis (◀ Section 14.6).

18.15 Red Algae

KEY GENERA: *Polysiphonia*, *Cyanidium*, *Galdiera*

The red algae, also called *rhodophytes*, mainly inhabit the marine environment, but a few species are found in freshwater and terrestrial habitats. Both unicellular and multicellular species are known, and some of the latter are macroscopic.

Major Properties of Red Algae

Red algae are phototrophic and contain chlorophyll *a*; their chloroplasts lack chlorophyll *b* but contain phycobiliproteins, the major light-harvesting pigments of the cyanobacteria (◀ Section 14.4). The reddish color of many red algae (Figure 18.32) results from phycoerythrin, an accessory pigment that masks the green color of chlorophyll. This pigment is present along with phycocyanin and

Figure 18.32 *Polysiphonia*, a filamentous marine red alga. Light micrograph. *Polysiphonia* grows attached to the surfaces of marine plants. Cells are about 150 μm wide.

allophycocyanin in structures called *phycobilisomes*, the light-harvesting (antenna) components of cyanobacteria. At greater depths in aquatic habitats, where less light penetrates, cells compensate by producing more phycoerythrin and are a darker red, whereas shallow-dwelling species often have less phycoerythrin and can be green in color (see Figure 18.33).

Most species of red algae inhabit marine environments and are multicellular and lack flagella. Some are “seaweeds” and are the source of agar, the solidifying agent used in bacteriological culture media, and carrageenans, thickening and stabilizing agents used in the food industry. Other species of red algae, such as the genus *Porphyra*, are harvested, dried, and used as a wrap in sushi. Different species of red algae are filamentous, leafy, or, if they deposit calcium carbonate, *coralline* (coral-like) in morphology. Coralline red algae play an important role in the development of coral reefs and help strengthen reefs against wave damage (► Section 23.13).

Polysiphonia (Figure 18.32) is a genus of filamentous and branched red algae found worldwide in marine environments. The organism is found primarily near shore where the cells grow attached to rocks, other algae, and man-made surfaces such as jetties, concrete abutments, retaining walls, and docks. Nearly 200 species of this genus are recognized, and the organism undergoes a complex life cycle in which an alternation of generations occurs. In this cycle, haploid male and female gametes released from a diploid multicellular organism develop into haploid male and female multicellular organisms. The male alga then releases haploid “sperm” cells that fuse with a specialized reproductive structure on the female alga to yield a diploid zygote; the latter develops a multicellular form and, following meiosis, releases male and female gametes to complete the life cycle.

Cyanidium, Galdieria, and Relatives

In addition to multicellular red algae like *Polysiphonia* (Figure 18.32), unicellular species are also known. One such group, members of the *Cyanidiales* that include the genera *Cyanidium*, *Cyanidioschyzon*, and *Galdieria* (Figure 18.33), live in hot, acidic and metal-rich hot springs

Figure 18.33 *Galdieria*, a unicellular red alga. (a) *Galdieria* inhabits acidic and sulfidic hot springs where it often grows attached to mineral debris as shown here (arrow). (b) Cells of *Galdieria* are about 25 μm in diameter and are more blue-green than red in color because the phototroph contains mainly phycocyanin rather than phycoerythrin as its phycobilin (◄ Section 14.4).

at temperatures from 30 to 60°C and acidic pH (0.5 to 4.0); under these extreme conditions, no other phototrophic microorganisms (including anoxygenic phototrophs) can exist. The unicellular red algae are unusual in other ways as well. For example, cells of *Cyanidioschyzon merolae* are unusually small (1–2 μm in diameter) for eukaryotes, and the genome of this species, approximately 16.5 Mbp, is one of the smallest genomes known for a phototrophic eukaryote.

Molecular analyses of the *Galdieria* genome have revealed the surprising result that this *eukaryotic* phototroph contains at least 75 genes acquired by horizontal transfer from various *prokaryotic* sources. Some of the key genes transferred encode protections against salt stress and metal toxicity and the construction of a toughened cytoplasmic membrane to withstand the heat and acidity of the *Galdieria* habitat (Figure 18.33a). The ability of *Galdieria* to grow in darkness—an unusual feature for an alga—has also been linked to horizontally transferred genes, in particular to genes encoding transport systems for various organic compounds. Although these genetic transfers are unusual in the sense that donor and recipient belong to different phylogenetic domains, they once again underscore the importance of horizontal gene transfer in molding microbial genomes (◄ Section 13.9).

Check Your Understanding

- What traits link cyanobacteria and red algae?
- What physiological properties would be necessary for *Galdieria* to live in its habitat?

18.16 Green Algae

KEY GENERA: *Chlamydomonas*, *Volvox*

The green algae, also called *chlorophytes*, have chloroplasts containing chlorophylls *a* and *b*, which give them their characteristic green color, but they lack phycobiliproteins and so do not develop the red

Figure 18.34 Green algae. (a) A single-celled, flagellated green alga, *Dunaliella*. A cell is about 5 μm wide. (b) The plantlike green alga *Chara*. (c) *Micrasterias*. This single multilobed cell is about 100 μm wide. (d) *Scenedesmus*, showing packets of four cells each. (e) *Spirogyra*, a filamentous alga with cells about 20 μm wide. Note the green spiral-shaped chloroplasts. (f) *Volvox carteri* colony with eight daughter colonies. (g) The petroleum-producing green alga *Botryococcus braunii*. Note the excreted oil droplets surrounding the cell.

or blue-green colors of red algae (Figures 18.32 and 18.33). In the composition of their photosynthetic pigments, green algae are similar to plants and are closely related to plants phylogenetically. There are two main groups of green algae, the *chlorophytes*, examples of which are the microscopic *Chlamydomonas* and *Dunaliella* (Figure 18.34a), and the charophyceans such as *Chara* (Figure 18.34b), macroscopic organisms that often resemble land plants and are actually most closely related to land plants.

Most green algae inhabit freshwater while others are found in moist soil or growing in snow, to which they impart a pink color (◀ Figure 4.23). Other green algae live with fungi in a symbiotic relationship to form lichens (▶ Section 23.1). The morphology of chlorophytes ranges from unicellular (Figure 18.34a, c), to filamentous (with individual cells arranged end to end, Figure 18.34e), to **colonial** (as aggregates of cells, Figure 18.34f). Even multicellular species exist, an example of which is the seaweed *Ulva*. Most green algae have a complex life cycle, with both sexual and asexual reproductive stages.

Very Small Green Algae and Colonial Green Algae

One of the smallest eukaryotes known is the green alga *Ostreococcus tauri*, a common unicellular species of marine phytoplankton

(▶ Section 20.11 and Figure 20.27b). Cells of *O. tauri* have a diameter of approximately 2 μm , and the organism contains the smallest genome of any known phototrophic eukaryote, approximately 12.6 Mbp. *Ostreococcus* has thus provided a model organism for research into the evolution of genome reduction and specialization in eukaryotes.

At the colonial level of organization in green algae is *Volvox* (Figure 18.34f). This alga forms colonies composed of several hundred flagellated cells, some of which are motile and primarily carry out photosynthesis, while others specialize in reproduction. Cells in a *Volvox* colony are interconnected by thin strands of cytoplasm that allow the entire colony to swim in a coordinated fashion. *Volvox* has been a long-term model for research on the genetic mechanisms controlling multicellularity and the distribution of functions among cells in multicellular organisms.

Some colonial green algae have potential as sources of biofuels. For example, the colonial green alga *Botryococcus braunii* excretes long-chain (C_{30} – C_{36}) hydrocarbons that have the consistency of crude oil (Figure 18.34g). About 30% of the *B. braunii* cell dry weight consists of this petroleum, and there has been heightened interest in using this and other oil-producing algae as renewable sources of petroleum. Evidence from biomarker studies has shown that some

Figure 18.35 Endolithic phototrophs. (a) Photograph of a limestone rock from the McMurdo Dry Valleys region of Antarctica broken open to show the layer of endolithic green algae. (b) Light micrograph of cells of the green alga *Trebouxia*, a widespread endolithic alga in Antarctica.

known petroleum reserves originated from green algae such as *B. braunii* that settled in lake beds in ancient times. Hence, if the scale-up challenges for commercial algal petroleum production could ever be met, it is possible that some fraction of the world's oil supply could someday come from photosynthesis by green algae.

Endolithic Phototrophs

Some green algae grow inside rocks. These *endolithic* (*endo* means “inside”) phototrophs inhabit porous rocks, such as those containing quartz, and are typically found in layers near the rock surface (Figure 18.35a). Endolithic phototrophic communities are most common in dry environments such as deserts or cold, dry environments such as Antarctica. For example, in the McMurdo Dry Valleys of Antarctica, where temperatures and humidity are extremely low (◀ Figure 4.22d, e), life within a rock has its advantages. Rocks in these harsh environments are heated by the sun, and water from snowmelt can be absorbed and retained for relatively long periods, supplying moisture needed for growth. Moreover, water absorbed by a porous rock makes the rock more transparent, thus funneling more light to the algal layers.

A wide variety of phototrophs can form endolithic communities, including cyanobacteria and various green algae (Figure 18.35b). In addition to being free-living phototrophs, green algae and cyanobacteria coexist with fungi in endolithic lichen communities (▶ Section 23.1 for discussion of the lichen symbiosis). Metabolism and growth of these internal rock microbial communities slowly weathers the rock, allowing gaps to develop where water can enter, freeze and thaw, and eventually crack the rock, producing new habitats for microbial colonization. The decomposing rock also forms a crude soil that can support development of plant and animal communities in environments where conditions (temperature, moisture, and so on) permit.

CHAPTER REVIEW

I • Organelles and Phylogeny of Microbial Eukarya

- 18.1** Key metabolic organelles of eukaryotes are the chloroplast, which functions in photosynthesis, and the mitochondrion, which functions in respiration. These organelles were originally *Bacteria* that established permanent residence inside other cells (endosymbiosis).

Q Distinguish between a primary and a secondary endosymbiosis. Which groups of protists are derived from which form of endosymbiosis?

- 18.2** The modern phylogeny of eukaryotes suggests a major radiation of eukaryotic diversity emerging at some time following symbiotic events that led to the mitochondrion. The latter provided eukaryotic cells with a

chemotrophic energy-generating powerhouse that is present today in nearly all eukaryotic cells.

Q What are the five major supergroups within the Eukarya?

II • Protists

- 18.3** Diplomonads such as *Giardia* are unicellular, flagellated, nonphototrophic protists. Parabasalids such as *Trichomonas* are human pathogens and contain huge genomes that lack introns. Euglenids and kinetoplastids are unicellular, flagellated protists. Some are phototrophic. This group includes some important human pathogens, such as *Trypanosoma*, and some well-studied nonpathogens, such as *Euglena*.

Q What are hydrogenosomes and what is their function?

- 18.4** Three groups make up the *Alveolata*: ciliates, dinoflagellates, and apicomplexans. Most ciliates and dinoflagellates are free-living organisms, whereas apicomplexans are obligate parasites of animals.

Q How are alveolates as a group characterized?

- 18.5** *Stramenopiles* are protists that bear a flagellum with fine, hairlike extensions. They include oomycetes, diatoms, and brown and golden algae.

Q In terms of their photosynthetic pigments, how are brown and golden algae similar?

- 18.6** The *Rhizaria* include diverse protists such as the phototrophic chlorarachniophytes and foraminiferans, as well as radiolarians, which are chemoorganotrophs.

Q How can *Rhizaria* be distinguished from other protists in their environment?

- 18.7** Haptophytes include the coccolithophores, unicellular phototrophic microbes that form intricate calcite exoskeletons. Coccolithophores such as *Emiliania huxleyi* are abundant in the oceans and important to global climate because they remove carbon from the atmosphere and deposit it as calcite in deep ocean sediments.

Q Describe the life cycle of *E. huxleyi* and explain why this life cycle can make it difficult to identify species of coccolithophores in the environment.

- 18.8** *Amoebozoa* are protists that use pseudopodia for movement and feeding. Within *Amoebozoa* are gymnamoebas, entamoebas, and slime molds. Plasmodial slime molds form masses of motile protoplasm, whereas cellular slime molds are individual cells that aggregate to form fruiting bodies from which spores are released.

Q Where are gymnamoebas found in nature? How do they feed?

III • Fungi

- 18.9** Fungi include the molds, mushrooms, and yeasts. Other than phylogeny, fungi primarily differ from protists by their rigid chitin-containing cell wall, production of spores, and the fact that most fungal species are nonmotile.

Q How can fungi benefit both plants and humans?

- 18.10** A variety of sexual spores are produced by fungi, including ascospores, basidiospores, and zygospores. From a phylogenetic standpoint, fungi are the closest relatives of animals.

Q List the different types of sexual spores of fungi. Are conidia sexual or asexual spores?

- 18.11** *Chytridiomycota* and *Microsporidia* are basal to all other known fungal groups in the fungal phylogeny. Some chytrids are amphibian pathogens, while microsporidians are parasites of a variety of animals.

Q In what way do chytrids and microsporidians differ from other fungi?

- 18.12** *Mucoromycota* form coenocytic hyphae and undergo both asexual and sexual reproduction, and the common bread mold *Rhizopus* is a good example. *Glomeromycota* are fungi that form endomycorrhizal associations with plants.

Q What is the major feature of the ecology of glomeromycetes?

- 18.13** The *Ascomycota* are a large and diverse group of mostly saprophytic fungi. Some, such as *Candida albicans*, can be pathogenic in humans. There are two mating types in the yeast *Saccharomyces cerevisiae*, and yeast cells can convert from one type to the other by a genetic switch mechanism.

Q How is the mating type of a yeast cell determined?

- 18.14** *Basidiomycota* include the mushrooms, puffballs, smuts, and rusts. Basidiomycetes undergo both vegetative (asexual) reproduction as haploid mycelia and sexual reproduction via fusion of mating types and formation of haploid basidiospores.

Q What morphological feature unites the *Basidiomycota*, and where is this feature found?

IV • Archaeplastida

- 18.15** Red algae are mostly marine and range from unicellular to multicellular. Their reddish color is due to the pigment phycoerythrin, a key cyanobacterial pigment, present in their chloroplast.

Q In what kinds of habitats would one likely find red algae?

- 18.16** Green algae are common in aquatic environments and can be unicellular, filamentous, colonial, or multicellular. A unicellular green alga, *Ostreococcus*, has the smallest genome known for a phototrophic eukaryote, while the green alga *Volvox* is a model colonial phototroph.

Q What traits link green algae and plants? What traits link green algae and red algae?

APPLICATION QUESTIONS

1. Explain the differences between mitochondria, chloroplasts, hydrogenosomes, and mitosomes. Explain the evolutionary process that gave rise to hydrogenosomes and mitosomes. Explain why the chloroplasts of red and green algae have two membranes, while those of many other photosynthetic protists have four membranes.
2. Considering all of the groups of microbes covered in this chapter, which of them seem most similar to prokaryotic cells in cell structure? Discuss at least two lines of evidence that show that these microbes are not prokaryotic cells.

CHAPTER GLOSSARY

Algae an informal term for phototrophic eukaryotes other than plants; algae are polyphyletic, being found in diverse groups of *Eukarya* as a result of secondary endosymbiosis

Chitin a polymer of *N*-acetylglucosamine commonly found in the cell walls of fungi

Ciliate any protist characterized in part by rapid motility driven by numerous short appendages called cilia

Coenocytic the presence of multiple nuclei in fungal hyphae without septa

Colonial the growth form of certain protists and green algae in which several cells live together and cooperate for feeding, motility, or reproduction; an early form of multicellularity

Conidia the asexual spores of fungi

Fungi nonphototrophic eukaryotic microorganisms with rigid cell walls made of chitin

Hydrogenosomes organelles that produce ATP through fermentation reactions resulting in the production of H₂ and acetate

Mushroom the aboveground fruiting body, or basidiocarp, of basidiomycete fungi

Nucleomorphs remnant nuclei found in certain algae; derived from an ancestral algal endosymbiont and associated with chloroplasts acquired by secondary endosymbiosis

Phagocytosis a mechanism for ingesting particulate material in which a portion of the cytoplasmic membrane surrounds the particle and brings it into the cell; for phagocytes of the immune system, the process of engulfing and killing foreign particles and cells

Primary endosymbiosis the endosymbiotic acquisition by a eukaryotic host cell of a respiring bacterium or a phototrophic

cyanobacterium, followed by evolution of the endosymbiont into mitochondria or chloroplasts

Protist an informal term used to describe eukaryotic microorganisms that are not plants, animals, or fungi; can be heterotrophic or phototrophic, unicellular or multicellular

Secondary endosymbiosis the endosymbiotic acquisition by a mitochondrion-containing eukaryotic cell of a red or green algal cell, which itself contains a chloroplast derived from primary endosymbiosis

Slime mold a nonphototrophic protist that lacks cell walls and that aggregates to form fruiting structures (cellular slime molds) or masses of protoplasm (acellular slime molds)

Yeast the single-celled growth form of various fungi

19 Taking the Measure of Microbial Systems

MICROBIOLOGYNOW

Touring Microbial Biogeography Using Combinatorial Imaging

Virtually all microorganisms exist as parts of complex communities that interact through metabolic cooperation. Since complex metabolic interactions are not easily resolved, the microscope is an essential tool for first identifying possible cooperation based on colocalization of different species. However, even the simplest of microbial communities is composed of tens if not hundreds of different species. How it is possible to visualize the distribution of individual species in such a mixture?

As we will see in this chapter, microscopic identification of species commonly uses fluorescence in situ hybridization (FISH), a technique in which cells of individual species are identified by hybridization of fluorescent DNA probes to ribosomal RNA sequences unique to each species. However, the method can visualize only a few different species simultaneously, being limited by the number of dyes that fluoresce in different colors. A variation on standard FISH technology that circumvents this limitation is called CLASI-FISH (combinatorial labeling and spectral imaging–FISH), which can image more than 100 different species simultaneously.

CLASI-FISH hybridizes each cell with a combination of probes specific for that species but labeled with different fluorescent dyes, giving each cell a unique fluorescent spectral signature. Since the resulting fluorescence at each wavelength is a linear combination of emissions from each fluorescent dye, statistical analysis can determine what combination of dyes produced the emission spectrum and therefore identify the contributing species.

The photo shown here was taken from a scraping of the human tongue (the specimen is about 140 μm in diameter, left to right), showing a remarkable organization of microbial species that almost certainly reflects metabolic interactions that can now be further explored using the powerful tools we discuss in this chapter. Brown in the photo is human tissue; the bacteria are: red, *Actinomyces* spp.; green, *Streptococcus* spp.; blue, *Rothia* spp.; yellow, *Neisseria* spp.; and magenta, *Veillonella* spp.

Source: Welch, J.L.M., Dewhirst, F.E., and Borisy, G.G. 2019. Biogeography of the oral microbiome: The site-specialist hypothesis. *Annu. Rev. Microbiol.* 73. doi: 10.1146/annurev-micro-090817-062503.

We now begin a new unit devoted to microorganisms in their natural habitats. We learned in Chapter 1 that microbial communities consist of cell populations living in association with other populations in nature. The science of **microbial ecology** is focused on how microbial populations assemble to form communities and how these communities interact with each other and their environments.

The major components of microbial ecology are *biodiversity* and *microbial activity*. To study biodiversity, microbial ecologists must identify and quantify microorganisms in their habitats. Knowing how to do this is often helpful for isolating organisms of interest as well, which is another goal of microbial ecology. To study microbial activity, microbial ecologists must measure the metabolic processes that microorganisms carry out in their habitats. In this chapter we consider modern methods for assessing microbial diversity and activity. Chapter 20 will outline the basic principles of microbial ecology and examine the types of environments that microorganisms inhabit. Chapters 21–24 will complete our coverage of microbial ecology by exploring nutrient cycles, applied microbiology, and the role microbes play in symbiotic associations with other life forms, including humans.

We begin with the microbial ecologist’s toolbox, which includes a collection of powerful tools for dissecting the structure and function of microbial communities in relation to their natural habitats.

I • Culture-Dependent Analyses of Microbial Communities

Major advances in molecular, microscopic, and analytical methods have revealed important properties of microorganisms as they exist in nature. However, to fully characterize a microbe, there is no substitute for isolating it in pure culture. In addition to traditional isolation methods, single-cell and high-throughput cultivation methods have greatly advanced success in culturing the “uncultured majority” of microorganisms.

The vast majority of microorganisms, more than 99% of all species by most estimates, have never been grown in laboratory cultures. To date, about 17,000 species of *Archaea* and *Bacteria* have been formally described. By contrast, culture-independent molecular

diversity surveys (Sections 19.4–19.8) indicate that many millions—possibly even trillions—of species exist in nature and have yet to be cultured and formally described. This recognition has stimulated the development of new methods for isolating microbes from nature in order to establish pure cultures. Even though a host of sophisticated methods are available for studying microbes in their native environments, culturing a microorganism remains the only way to fully characterize its properties and predict its impact on its environment.

In the first part of this chapter we cover the enrichment approach, a time-honored and useful method for isolating microorganisms from nature, but a method with significant limitations. Enrichment is based on culturing in a selective growth medium, and thus the tools and methods used in this approach are considered *culture-dependent* analyses. As we will see, considerable progress has been made in culturing the more elusive microorganisms in natural populations by using robotics and associated microfabrication technology to establish large numbers of enrichment cultures that can be monitored simultaneously. In the second and third parts of this chapter we consider *culture-independent* analyses, techniques that can tell us much about the structure and function of microbial communities in the absence of actual laboratory cultures. In the final part of this chapter, we consider methods for measuring microbial activities in nature and linking them to specific organisms. Collectively, these methods allow the microbial ecologist to ask both “Who is there?” and “What are they doing?”

19.1 Enrichment Culture Microbiology

For an **enrichment culture**, a medium and a set of incubation conditions are established that are *selective* for the desired organism and *counterselective* for undesired organisms. Effective enrichment cultures duplicate as closely as possible the resources and conditions of a particular ecological niche. Hundreds of different enrichment strategies have been devised, and **Tables 19.1** and **19.2** summarize some simple and direct ones.

Inocula

Successful enrichment requires an appropriate inoculum containing the organism of interest. Thus, the making of an enrichment culture

TABLE 19.1 Some enrichment culture methods for phototrophic bacteria (main C source, CO ₂)		
Incubation condition	Organisms enriched	Inoculum
Incubation in air		
N ₂ as nitrogen source	Cyanobacteria	Pond or lake water; sulfide-rich muds; stagnant water; raw sewage; moist, decomposing leaf litter; moist soil exposed to light
NO ₃ [−] as nitrogen source, 55°C	Thermophilic cyanobacteria	Hot spring microbial mat
Anoxic incubation		
H ₂ or organic acids; N ₂ as sole nitrogen source	Purple nonsulfur bacteria, heliobacteria	Same as above plus hypolimnetic lake water (► Section 20.9); pasteurized soil (heliobacteria); microbial mats for thermophilic species
H ₂ S as electron donor	Purple and green sulfur bacteria	
Fe ²⁺ , NO ₂ [−] as electron donor	Purple bacteria	

TABLE 19.2 Some enrichment culture methods for nonphototrophic bacteria ^a			
Electron acceptor	Electron donor and nitrogen source	Typical organisms enriched	Inoculum source
Chemoorganotrophs			
Aerobes			
O ₂	Lactate, benzoate + NH ₄ ⁺	<i>Mycobacterium</i> , <i>Nocardia</i> , <i>Pseudomonas</i>	Soil, mud, lake sediments, decaying vegetation
	Hydrocarbons, toluene + NH ₄ ⁺	<i>Mycobacterium</i> , <i>Nocardia</i> , <i>Pseudomonas</i>	
	Mannitol or benzoate, N ₂ as nitrogen	<i>Azotobacter</i>	
	Ethanol + yeast extract, pH 6.0	<i>Acetobacter</i> , <i>Gluconobacter</i>	
	Cellulose + NH ₄ ⁺	<i>Cytophaga</i> , <i>Sporocytophaga</i>	
	CH ₄ + NO ₃ [−]	<i>Methylobacter</i> , <i>Methylomicrobium</i>	Lake sediments, thermocline of stratified lake
Chemoorganotrophs			
Anaerobic respiration and fermentation			
NO ₃ [−]	Organic acids + NO ₃ [−]	<i>Pseudomonas</i> (denitrifying species)	Soil, mud, lake sediments, groundwater seeps, sediments, pasteurized inoculum (80°C for 15 min) for <i>Bacillus</i> enrichments
	Yeast extract + NO ₃ [−]	<i>Bacillus</i> (denitrifying species)	
ClO ₃ [−]	Acetate	Various (per)chlorate-reducing <i>Bacteria</i> and <i>Archaea</i>	Contaminated groundwater, rivers, soils, sediments, wastewater treatment systems
PCE	Acetate + H ₂ + NH ₄ ⁺	<i>Dehalococcoides</i> spp.	Tetrachloroethene (PCE)-polluted groundwater
SO ₄ ^{2−}	Lactate, ethanol, organic acids	<i>Desulfovibrio</i> , <i>Desulfotomaculum</i>	Soil, mud, sediments, sewage sludge
	Acetate, propionate, butyrate	Fatty acid-oxidizing sulfate reducers	
S ⁰	Acetate, ethanol	<i>Desulfuromonas</i>	Soil, mud, sediments, sewage sludge
None	Acetate	<i>Methanosarcina</i> , <i>Methanosaeta</i>	Mud, lake sediments, rotting plant or animal material, dairy products (lactic and propionic acid bacteria); rumen or intestinal contents (enteric bacteria); sewage sludge; soil, pasteurized inoculum for <i>Clostridium</i> enrichments
	Glutamate or histidine	Proteolytic <i>Clostridium</i> species	
	Starch + NH ₄ ⁺	<i>Clostridium</i> spp.	
	Starch + N ₂ as nitrogen source	<i>Clostridium pasteurianum</i>	
	Lactate + yeast extract	<i>Veillonella</i> spp.	
	Glucose + yeast extract (pH 5)	Lactic acid bacteria (<i>Lactobacillus</i>)	
	Succinate + NaCl	<i>Propionigenium</i>

Chemolithotrophs			
Anaerobes			
Fe ⁺³	Acetate	<i>Geobacter</i> , <i>Geospirillum</i>	Groundwater
NO ₃ [−]	Fe ⁺² + NO ₃ [−]	Iron-oxidizing chemolithotrophs	Groundwater, groundwater seeps, sediments
	S ⁰ , S ₂ O ₃ ^{2−}	<i>Thiobacillus denitrificans</i>	Mud, lake sediments, soil
	H ₂	<i>Paracoccus denitrificans</i>	
CO ₂	H ₂ + NH ₄ ⁺	Methanogens (chemolithotrophic species only), homoacetogens	Mud, lake sediments, rotting plant or animal material, rumen or intestinal contents, sewage sludge

^aAll media must contain an assortment of mineral salts including N, P, S, Mg²⁺, Mn²⁺, Fe²⁺, Ca²⁺, and other trace elements (◀ Sections 4.1, 4.2). Certain organisms may have requirements for vitamins or other growth factors. This table is a general overview of enrichment methods focused on substrates and atmospheric conditions and has not considered the effects that temperature, pH and salinity can have on enrichment culture outcomes.

^bComammox is the complete oxidation of ammonia all the way to nitrate (▶ Section 20.3).

begins with collecting a sample from the appropriate habitat to serve as the inoculum (Tables 19.1 and 19.2). Enrichment cultures are established by placing the inoculum into selective media and incubating under specific conditions. In this way, many common microbes can be isolated. For example, the great Dutch microbiologist Martinus Beijerinck, who conceptualized the enrichment culture technique (◀ Section 1.13), used enrichment cultures to isolate the nitrogen-fixing bacterium *Azotobacter* (Figure 19.1). Because *Azotobacter* is a rapidly growing bacterium capable of N_2 fixation in air (◀ Sections 3.12 and 15.9), enrichment using media devoid of fixed nitrogen (for example, ammonia or nitrate) and incubation in air selects strongly for this bacterium and its close relatives. Non-nitrogen-fixing bacteria and anaerobic nitrogen-fixing bacteria are counterselected in this technique.

Enrichment Culture Outcomes

For success with enrichment cultures, attention to both the culture medium and the incubation conditions is important. That is, the *resources* (nutrients) and *conditions* (temperature, pH, osmotic considerations, aerobic or anaerobic, and the like) must closely mimic those of the habitat to offer the best chance of obtaining the organism of interest (▶ Table 20.1).

Figure 19.1 The isolation of *Azotobacter*. Selection for aerobic nitrogen-fixing bacteria usually results in the isolation of *Azotobacter* or its relatives. The selective basis of the enrichment is the absence of fixed nitrogen (NH_4^+ in this case) in the culture medium in the upper flask. Thus the medium *selects* from the microbial community those species that can fix N_2 aerobically, of which *Azotobacter* is one of the most rapidly growing. See Section 1.13 and Figure 1.37 for more on the historical importance of *Azotobacter*.

Some enrichment cultures yield nothing. This may be because an organism capable of growing under the enrichment conditions established is absent from the habitat. Alternatively, even though the organism of interest exists in the habitat sampled, the resources and conditions employed in the enrichment may simply be incompatible with its growth. Thus, enrichment cultures can yield a firm *positive* conclusion (that is, that an organism with certain capacities exists in a particular environment because it was enriched) but never a firm *negative* conclusion (that such an organism is not present because the enrichment failed). Moreover, the isolation of the desired organism from an enrichment culture says nothing about the abundance or ecological significance of the organism in its habitat. A positive enrichment proves only that the organism was present in the sample, and in practice, this can result from even a single viable cell.

The Winogradsky Column

The **Winogradsky column** is an artificial microbial ecosystem and a long-term source of various bacteria for enrichment cultures. Winogradsky columns have been used to isolate phototrophic purple and green bacteria, sulfate-reducing bacteria, and many other anaerobes. Named for the famous Russian microbiologist Sergei Winogradsky (◀ Section 1.13), the column was first used by Winogradsky in the late nineteenth century in his classic studies of soil microorganisms.

A Winogradsky column is prepared by filling a glass cylinder about half full with organic-rich, preferably sulfidic mud into which carbon substrates have been mixed. The substrates determine which organisms are enriched. Fermentative substrates, such as glucose, that can lead to acidic conditions and excessive gas formation (which can create gas pockets that disrupt the enrichment culture and let in air) are avoided. The mud is supplemented with small amounts of calcium carbonate ($CaCO_3$) as a buffer and gypsum ($CaSO_4$) as a source of sulfate. The mud is packed tightly in the cylinder, taking care to avoid trapping air, and then covered with lake, pond, or ditch water (or seawater if it is a marine column). The top of the cylinder is covered to prevent evaporation, and the container is placed near a window that receives diffuse sunlight for a period of months.

In a typical Winogradsky column, a diverse community of microbes develops (Figure 19.2a). Algae and cyanobacteria develop quickly in the upper portions of the water column; by producing O_2 these organisms help to keep this zone of the column oxic much as they do in the upper zones of a lake. Fermentative processes in the mud lead to the production of organic acids, alcohols, and H_2 , suitable substrates for sulfate-reducing bacteria (◀ Section 15.11). Hydrogen sulfide (H_2S) from the sulfate reducers triggers the development of purple and green sulfur bacteria (anoxygenic phototrophs, ◀ Sections 14.3 and 15.4–15.8) that use sulfide as a photosynthetic electron donor. These organisms typically grow in patches in the mud on the sides of the column but may bloom in the water itself if anoxygenic phototrophs are scarce (Figure 19.2b). The pigmented cells of the anoxygenic phototrophs can be sampled with a pipette for microscopy, isolation, and characterization (Table 19.1).

Winogradsky columns have been used to enrich both aerobic and anaerobic *Bacteria* and *Archaea*. Besides supplying a ready source of inocula for enrichment cultures, columns can also be supplemented

with a specific compound to enrich an organism in the inoculum that can degrade it. Once a crude enrichment has been established in the column, culture media can be inoculated for the isolation of pure cultures, as discussed in Section 19.2.

Enrichment Bias

Although the enrichment culture technique is quite useful and still widely practiced, there exists a bias, and sometimes a very severe bias, in the outcome of enrichments. This bias is typically most profound in liquid enrichment cultures where the most rapidly growing organism(s) for the chosen set of conditions dominate. However, using molecular techniques to be described later, we now know that the most rapidly growing organisms in laboratory cultures are often only minor components of the microbial community rather than the most abundant and ecologically relevant organisms carrying out the process of interest. This could be for several reasons including the fact that the levels of resources available in laboratory cultures are typically much higher than those in nature, and the conditions in the natural habitat, including both the types and proportions of different organisms present as well as the physical and chemical conditions, are nearly impossible to reproduce and maintain for long periods in laboratory cultures.

This problem of **enrichment bias** can be demonstrated by comparing the results obtained in dilution cultures (Section 19.2) with classical liquid enrichment. Dilution of an inoculum followed by liquid enrichment or plating often yields different organisms than

liquid enrichments established with the same but undiluted inocula. It is thought that dilution of the inoculum eliminates quantitatively insignificant but rapidly growing “weed” species, allowing development of organisms that are more abundant in the community but slower growing. Dilution of the inoculum is thus a common practice in enrichment culture microbiology today. As discussed below, the problem of overgrowth by “weed” species can also be circumvented by physical isolation of the desired organism before introducing it into a growth medium. This can be accomplished by dilution and a variety of classical isolation procedures that we turn to in the next section. However, more recently, sophisticated methods have been developed to physically isolate single cells of interest (or a single type of cells) and place them in a growth medium that is free of undesired cells. We consider these techniques in Section 19.3. Finally, as we will discuss later in this chapter, culture-independent molecular methods have most clearly revealed the limitations of cultivation in capturing the full microbial diversity of most environments.

- Why is sulfate (SO_4^{2-}) added to a Winogradsky column?
- What is enrichment bias? How does dilution reduce enrichment bias?

19.2 Classical Procedures for Isolating Microbes

Once a positive enrichment culture has been obtained, the next step is typically to attempt to get the enriched organism in *pure culture*—one containing a single kind of microorganism. Pure cultures are valuable because genomes can be quickly isolated and analyzed and experiments can be done under controlled laboratory conditions to clearly define the physiology of the isolate. Pure cultures have been studied since the days of Robert Koch (◀ Section 1.12), and we considered some of these methods earlier (◀ Section 4.2).

Agar Dilution Tubes and the Most-Probable-Number Technique

Common isolation procedures include the streak plate, agar dilution, and liquid dilution. For organisms that form colonies on agar plates, the streak plate is quick, easy, and the method of choice (Figure 19.3a); if a well-isolated colony is selected and restreaked several successive times, a pure culture is usually obtained. With proper incubation facilities (for example, anoxic jars or anoxic chambers for anaerobes, ▶ Section 4.16), it is possible to purify both aerobes and anaerobes on agar plates by the streak plate method.

In the agar dilution tube method, a mixed culture is diluted in tubes of molten agar medium, resulting in colonies embedded in the agar. This method is useful for purifying anaerobic organisms such as phototrophic sulfur bacteria and sulfate-reducing bacteria from samples taken from Winogradsky columns or other sources. A culture is purified by successive dilutions of cell suspensions in tubes of molten agar medium (Figure 19.3b, ▶ Figure 15.28g). Repeating this procedure using a colony from the highest-dilution tube as inoculum for a new set of dilutions usually yields pure cultures. A related procedure called the *roll tube method* uses tubes containing a thin layer of agar on their inner surface. The agar can then be streaked for isolated colonies. Because the tubes can be flushed with an oxygen-free gas during streaking, the roll tube method is primarily used for the isolation of anaerobic microbes.

Another purification procedure is the serial dilution of an inoculum in a liquid medium until the final tube in the series shows no growth. When a 10-fold serial dilution is used, for example, the last tube showing growth should have originated from ten or fewer cells. Besides being a method for obtaining pure cultures, serial dilution techniques are widely used to estimate viable cell numbers in the **most-probable-number (MPN) technique** (Figure 19.4). MPN methods have been used for estimating the numbers of microorganisms in foods, wastewater, and other samples in which cell numbers need to be assessed routinely. An MPN count of a natural sample can be done using highly selective media and incubation conditions to target one or a small group of organisms or a particular pathogen. Alternatively, a count can be done using complex media to get a general estimate of viable cell numbers (but see Section 4.4 for a caveat that applies to such estimates). Use of several replicate tubes at each dilution improves accuracy of the final MPN obtained.

Criteria for Culture Purity

Regardless of the methods used to purify a culture, once a putative pure culture has been obtained, it is essential to verify its purity. This is typically done through a combination of (1) microscopy, (2) observation

(a) Colonies Paraffin-mineral oil seal

(b)

Figure 19.3 Pure culture methods. (a) Organisms that form distinct colonies on plates are usually easy to purify. (b) Colonies of phototrophic purple bacteria in agar dilution tubes; the molten agar was cooled to approximately 45°C before inoculation. A dilution series was established from left to right, eventually yielding well-isolated colonies. The tubes were sealed with a 1:1 mixture of sterile paraffin and mineral oil to maintain anaerobiosis.

of colony characteristics on plates or in dilution tubes, and (3) tests of the culture for growth in other media. In the latter, it is important to test the culture for growth in media and under growth conditions in which the desired organism is predicted to grow poorly or not at all but in which contaminants will grow vigorously. In the final analysis, the microscopic observation of a single morphological type of cell that displays uniform staining characteristics (for example, in a Gram stain) coupled with uniform colony characteristics and the absence of contamination in growth tests with various culture media is strong evidence that a culture is a pure (*axenic*) culture.

Certain molecular methods described in this chapter for characterizing natural microbial communities can also be applied to the verification of culture purity. However, these techniques are complementary and do not substitute for the more fundamental observations of culture characteristics and cellular morphology.

Figure 19.4 Procedure for a most-probable-number (MPN) analysis. Growth in the 10^{-4} but not the 10^{-5} dilution means that cell numbers were at least 10^4 cells/ml in the sample used for inoculation. Because particle-attached microorganisms can skew numbers significantly, gentle methods to disassociate microorganisms from particles are often used prior to dilution. In addition, each dilution tube is mixed thoroughly before removing a sample for the next dilution.

- How does the agar dilution method differ from streaking to obtain isolated colonies?
- Why would microscopic examination alone not be sufficient to establish that a culture is pure?

19.3 Selective Single-Cell Isolation: Laser Tweezers, Flow Cytometry, Microfluidics, and High-Throughput Methods

The problem of enrichment bias has fueled the development of new methods for culturing microbes from nature. These advancements have emerged from the understanding that every microbe has a *fundamental niche* and a *realized niche*. The **fundamental niche** refers to the range of environments in which a species will be sustained when it is not resource-limited, such as may result from competition with other species. By contrast, the **realized niche** refers to the range of natural environments supporting a species when it is confronted with factors such as resource limitation, predation, and competition from other species.

Establishing laboratory conditions that fall within the fundamental niche may be sufficient to support an organism once it is in pure culture but may fail to selectively enrich the same organism from a natural sample. Because the realized niche of most microorganisms is unknown, there has been an increasing emphasis on developing methods that physically isolate single cells into separate compartments free from competition with other microbes. These include both manual and robotic methods that function to sort individual cells from an environmental sample, and we consider these methods now.

Laser Tweezers and Flow Cytometry

Laser tweezers consist of an inverted light microscope equipped with a strongly focused infrared laser and a micromanipulation device. Trapping a single cell is possible because the laser beam creates a force that pushes down on a microbial cell (or other small object) and holds it in place (**Figure 19.5a**). Then when the laser beam is moved, the trapped cell moves along with it. If a mixed sample is in a capillary tube, a single cell can be optically trapped and moved away from contaminating organisms (**Figure 19.5b**). The cell can then be isolated by breaking the tube at a point between the cell and the contaminants and flushing the cell into a small tube of sterile medium. Laser tweezers, when coupled with staining techniques that identify particular organisms (**Sections 19.4 and 19.5**), can be used to select organisms of interest from a mixture for purification and further laboratory study.

Flow cytometry is a technique for counting and examining a mixture of cells by suspending them in a stream of fluid and passing them through an electronic detector that sorts them according to defined criteria; for example, by cell size, shape, or fluorescent properties. This ability makes cell sorting useful not only for isolating single cells but also for enriching a particular cell type from a mixture. Cell sorters can deposit individual cells into wells of a microtiter plate where each well contains the same growth medium or a slightly different growth medium. Because the growth requirements

Figure 19.5 The laser tweezers for the isolation of single cells. (a) Mechanism by which individual cells can be isolated. (b) Once a cell has been isolated in a capillary tube, it can be tested for subsequent growth in pure culture.

of some organisms include organic compounds and metabolites produced by other organisms that share their environment, addition of filter-sterilized source water (for aquatic organisms) or soil water extract (for soil organisms) can be used to supplement the media tested. Each well in the microtiter plate can then be monitored for growth or some other property either manually or using robotic methods (high-throughput culture, see next subsection). We explore the mechanism and uses of flow cytometry in more detail in Section 19.12 (see Figure 19.42).

High-Throughput Culture and Microfluidic Devices

Continuing innovations in single-cell isolation methodology have spawned **high-throughput culturing methods** and related methods for use on an even smaller scale. High-throughput methods require dilution (or cell sorting) of a sample to yield a single cell in each well of a microtiter plate (Figure 19.6). From there, each well is robotically monitored over time for cell growth or a specific target gene. High-throughput methods allow the experimenter to test many alternative sets of resources and growth conditions systematically in an attempt to replicate the realized niche or, alternatively, to allow the organism to occupy its fundamental niche by relieving it from competition. Microtiter wells that are positive for cell growth or a target gene of interest identify the acceptable resources and conditions for growth of a particular microbe and supply valuable

clues for the design of laboratory culture media to obtain its growth in pure culture.

High-throughput cultivation has shown increasing success in isolating unique bacteria. For example, high-throughput methods were used for the isolation of one of the most abundant bacteria on Earth, the small marine planktonic bacterium *Pelagibacter ubique* (Figure 19.6). This bacterium thrives on the very dilute pool of dissolved organic matter present in the open oceans and eluded classical enrichment methods for years. But with high-throughput technology, this ecologically important bacterium was brought into laboratory culture where its biology could be studied in more detail.

Microfluidic devices carry the high-throughput concept even further by using microfabrication technology to combine channels and wells for fluid transfer and collection on a miniaturized platform. One such device is less than 10 centimeters long yet holds 3200 nanoliter-sized wells, with each well serving as a small culture vessel (Figure 19.7). An environmental sample is introduced into the microfluidic device such that each well receives a single cell. Different medium formulations can be tested, and the media supplemented with a small amount of filter-sterilized water or soil extract collected from the sampled environment (these additions may stimulate growth by providing trace nutrients missing in the culture medium).

Both cell growth and target genes can be assessed in each well of the microfluidic device; growth is assessed by direct microscopic

(b) Following the addition of filter-sterilized seawater and low nutrient concentrations to the individual wells, and deposition of single cells into individual wells of the microtiter plate, pure cultures of *Pelagibacter* and other novel marine *Bacteria* were obtained. *Pelagibacter* is the most abundant bacterium in the open oceans (► Section 20.12).

Figure 19.7 Microfluidic platform for cultivation. An environmental inoculum is suspended in a cultivation medium and loaded onto this microfluidic device, enabling confinement of as many as 3200 single cells in nanoliter wells to promote the growth of microcolonies. Following different periods of incubation, cultured populations are collected at the outlet and further grown under conditions demonstrated to support growth on the microfluidic device. The device is about 7 cm wide.

examination of cell numbers in a well under the microscope. If insufficient cellular biomass is available for molecular characterization of specific target genes by methods such as PCR (see Section 19.6), genome amplification as described for single-cell genomics (◀ Section 10.11) can be used prior to further analysis.

A variation on the microfluidics technique employs a microchamber device modified such that each of the tiny chambers is separated from the external environment by a membrane that traps the microbes but allows soluble nutrients to diffuse in and out. Following the introduction of a single cell into each chamber, the device is placed back into the environment from which the inoculum was obtained. Then, after incubation for a month or more, microbes that initiate growth only when incubated under the conditions and resources present in their habitats can often be isolated and subsequently propagated in the laboratory.

Although technology is rapidly advancing the art of isolating new microbes, patience is still needed in any cultivation effort, as the discovery of slow-growing or dormant organisms may require months of incubation. Also, many microbes in nature are likely adapted to extremely low nutrient concentrations and may be inhibited by levels of nutrients used to grow organisms commonly studied in the laboratory. Both high-throughput and microfluidic methods overcome these problems by their ability to separate individual cells from other cells that may release inhibitory materials and by surveying a nearly limitless variety of nutrient conditions. Currently, these methods offer the best opportunity for culturing the most interesting (and likely ecologically relevant) microorganisms from nature.

- What is meant by “high-throughput” in culturing microorganisms? How has it benefited microbiology?

II • Culture-Independent Microscopic Analyses of Microbial Communities

The microscope has been the microbiologist’s foremost tool for studying microbial structure. Today the microscope can also assist in probing microbial diversity and activity, thanks to a suite of fluorescent techniques. These advances have greatly improved our understanding of microbial community structure and provided unprecedented insight into microbial symbiotic relationships with plants, animals, and other microbes.

Microbial ecologists quantify cells in a microbial habitat to estimate abundance of the entire community or, more specifically, relative abundances of the different species in the community. Cell stains are necessary to obtain these types of data, and we detail these methods here. Organisms in natural environments can also be detected by assaying their genes. Genes encoding either ribosomal RNA (rRNA, ◀ Section 13.11) or enzymes that support a specific physiology are the usual targets in these studies. A rapidly developing approach to the study of microbial ecology, called *multi-omics*, combines multiple molecular, analytical, and omics methods (Chapter 10), and is introduced in Section 19.8.

19.4 General Staining Methods

Several general staining methods are suitable for quantifying microorganisms in natural samples. Although these methods do not reveal the physiology or phylogeny of the cells, they are nonetheless reliable and widely used by microbial ecologists for measuring total cell numbers. One method also allows cell viability to be assessed.

Fluorescent Staining with Dyes That Bind Nucleic Acids or Reveal Viability

Fluorescent dyes can be used to stain microorganisms from virtually any microbial habitat. **DAPI** (4',6-diamidino-2-phenylindole) is a popular stain for this purpose, as is the dye **acridine orange**. There is also increasing use of *SYBR Green I*, a dye that confers very bright fluorescence to all microorganisms, including viruses. These stains bind to DNA and are strongly fluorescent when exposed to ultraviolet (UV) radiation (DAPI absorption maximum, 400 nm; acridine orange absorption maximum, 500 nm; SYBR Green I absorption maximum, 497 nm), making the microbial cells in the sample readily visible and easy to enumerate. Cells stained with DAPI fluoresce blue, cells stained with acridine orange fluoresce orange or greenish-orange, and cells stained with SYBR Green I fluoresce green (Figure 19.8).

Dyes that stain DNA are widely used for the enumeration of microorganisms in environmental, food, and clinical samples. Depending on the sample, background staining is occasionally a problem with fluorescent stains, but because these dyes specifically stain nucleic acids, they are for the most part nonreactive with inert matter. Thus, for many samples, from soil as well as aquatic sources, they can give a reasonable estimate of the cell numbers present. Staining with the brightly fluorescent SYBR Green I also

Figure 19.8 Nonspecific fluorescent stains. (a) DAPI and (b) acridine orange staining showing microbial communities inhabiting activated sludge in a municipal wastewater treatment plant. With acridine orange, cells containing low RNA levels stain green. (c) SYBR Green–stained sample of Puget Sound (Washington, USA) surface water showing green-fluorescing bacterial cells. The large cells near the center of the field are 0.8–1.0 μm in diameter.

provides excellent enumeration of aquatic virus populations (► Section 20.13). For dilute aquatic samples, cells can be stained following collection on a membrane surface by filtration.

DNA staining is a nonspecific process; *all* microorganisms in a sample are stained. Although this may at first seem desirable, it is not necessarily so. For example, DAPI and acridine orange fail to differentiate between living and dead cells or between different species of microorganisms, so they cannot be used to assess cell viability or to track specific microorganisms in an environment. *Viability staining* solves one of these problems because it differentiates live cells from dead ones. Hence, viability stains yield both abundance and viability data at the same time. The basis of differentiating between live and dead cells lies not with a cell's DNA but whether its cytoplasmic membrane is intact or not. Two dyes that fluoresce green and red are added to a sample; the green-fluorescing dye penetrates all cells, viable or not, whereas the red dye, which contains the chemical propidium iodide, penetrates only those cells whose cytoplasmic membrane is no longer intact and that are therefore dead. Thus, when viewed microscopically, green cells are scored as alive and red cells as dead, yielding an instant assessment of both abundance and viability (Figure 19.9).

Figure 19.9 Viability staining. Live (green) and dead (red) cells of *Micrococcus luteus* (cocci) and *Bacillus cereus* (rods) stained by the LIVE/DEAD BacLight Bacterial Viability Stain.

Although useful for research that uses laboratory cultures, the live/dead staining method is not suitable for use in the direct microscopic examination of samples from many natural habitats because of problems with nonspecific staining of background materials. However, procedures have been developed to overcome this problem in analyses of aquatic environments; the water sample is filtered, and the filters are stained with the live/dead stain and examined microscopically. Thus in aquatic microbiology, live/dead staining is often used to measure the viability of cell populations in the water column of lakes or oceans, or in the flowing waters of streams, rivers, and other aquatic environments.

Fluorescent Proteins as Cell Tags and Reporter Genes

Bacterial cells can be altered by genetic engineering to make them autofluorescent. As discussed earlier, a gene encoding the **green fluorescent protein (GFP)** can be inserted into the genome of virtually any cultured bacterium (◀ Sections 8.1 and 12.5). When the gene encoding the GFP (*gfp*) is expressed, cells fluoresce green when observed with ultraviolet microscopy (Figure 19.10; ▶ Figure 12.17). Although GFP is not useful for the study of natural populations of microorganisms (because these cells lack the GFP gene), GFP-tagged cells can be introduced into an environment, such as plant roots, and then tracked over time by microscopy. Using this method, microbial ecologists can study competition between the native microbiota and a GFP-tagged introduced strain and can assess the effect of perturbations of an environment on the survivability of the introduced strain.

The gene *gfp* and those encoding other **fluorescent proteins** have also been used extensively in laboratory cultures of various bacteria and in controlled environments as *reporter genes*. When the gene is fused with an operon under the control of a specific regulatory protein, transcription can be studied by using fluorescence as the indicator (a “reporter”) of activity. That is, when genes containing the fused fluorescent protein gene are transcribed and translated, both the protein of interest and the fluorescent protein are made, and cells fluoresce the characteristic color. For example, expression of *gfp* was used to demonstrate that colonization of alfalfa roots by the nitrogen-fixing symbiotic bacterium *Sinorhizobium meliloti* (legume–root nodule symbiosis, ► Section 23.4) is promoted by sugars and dicarboxylic acids released by the plant (Figure 19.10b, c). The

Figure 19.10 Fluorescent protein reporters. (a) Twelve different fluorescent proteins (FP1–FP12) are known that have distinct excitation (Excite) and emission (Emit) properties. (b) Cells of *Sinorhizobium meliloti* (arrows) carrying a plasmid with an α -galactoside-inducible promoter fused to the GFP (FP5); the cells are on clover seedling roots. Green fluorescence indicates that α -galactosides are released and available to support the growth of this bacterium. (c) *S. meliloti* cells (arrows) carrying a plasmid with a succinate-inducible promoter fused to GFP; green fluorescence indicates that succinate or other C_4 dicarboxylic acids have been secreted by the plant root hairs.

emission properties of GFP and other fluorescent proteins isolated from different marine invertebrates (jellyfish, corals, anemones) have since been altered through mutation to yield a broad palette of fluorescent proteins of varying spectral properties (Figure 19.10a), offering the experimenter the capability to monitor several species simultaneously.

One drawback to the use of GFP is that to become fluorescent it requires O_2 , and thus it is not suitable for tracking cells introduced into strictly anoxic habitats. However, flavin-based fluorescent proteins that do not require O_2 are available to overcome this limitation. These proteins are derived from bacterial and plant photosensory flavoproteins and are more thermally stable than the GFP, making them useful for tracking mildly thermophilic species. In addition to these fluorescent tags for tracking microbes, phylogenetic stains (Section 19.5) are widely used for identifying microbes, and a wide variety of new fluorescent “super-resolution” microscopy techniques are available for tracking individual molecules within a microbial cell (◀ Section 8.1). Thus, fluorescence technology has come a long way since the days when only DAPI and acridine orange were available for visualizing microbial cells in nature.

- Why is it incorrect to say that the GFP is a “staining” method?

19.5 Microscopic Specificity: Fluorescence In Situ Hybridization (FISH)

As we have just seen, the microscope is an essential tool for enumerating and assaying microorganisms in a general way—their morphology, their Gram reaction, their viability, and the like. However,

the biggest limitation with the methods we have discussed thus far is that none of them reveal the *phylogeny* of the microorganisms observed under the microscope. That is, how many species, or phyla, or even domains, are present in the sample? More specific fluorescent staining methods are required to answer these questions.

When observing unstained or nonspecifically stained natural populations of microorganisms under the microscope (Section 19.4), one should remember that the sample likely contains a phylogenetically diverse community, even if many cells “look” the same. This is because the simple shapes of bacteria can conceal their remarkable diversity, and Figure 19.11 shows an

Figure 19.11 Morphology and genetic diversity. The photomicrographs shown here, produced by (a) phase contrast and (b) a technique called phylogenetic FISH (Section 19.5), are of the same field of cells. Although the large oval cells are of a rather unusual size for prokaryotic cells and all look similar by phase-contrast microscopy, the phylogenetic stains reveal that there are two genetically distinct types (one stains yellow and one stains blue). Both cell types are about $2.3\ \mu\text{m}$ in diameter. The smaller, green cells in pairs or clusters are about $1\ \mu\text{m}$ in diameter.

Figure 19.12 Fluorescently labeled rRNA probes: Phylogenetic stains. (a) Phase-contrast photomicrograph of cells of *Bacillus megaterium* (rod, *Bacteria*) and the yeast *Saccharomyces cerevisiae* (oval cells, *Eukarya*). (b) Same field; cells stained with a yellow-green universal rRNA probe (this probe hybridizes with rRNA from organisms of any phylogenetic domain). (c) Same field; cells stained with a eukaryal probe (only cells of *S. cerevisiae* react). Cells of *B. megaterium* are about 1.5 μm in diameter and cells of *S. cerevisiae* are about 6 μm in diameter.

example of this. The two photos are of the same microscope field, one taken in black and white of cells in a microbial community and the other taken in color of the same cells stained in a way that reveals their phylogeny. If only unstained cells (Figure 19.11a) were viewed, it would be easy to conclude that the large ovoid-shaped cells are all of a single species. But staining to reveal phylogeny (Figure 19.11b) shows that they are not; the blue and yellow fluorescent stains target different species of large ovoid cells while the green stain reveals yet a third species in the community. Microscopic assessments of phylogenetic diversity such as this can only be made using *phylogenetic stains*, and we consider these here along with some related staining techniques.

Phylogenetic Identification Using FISH

Because of their great specificity, **nucleic acid probes** can be harnessed as powerful tools for identifying and quantifying microorganisms. Recall that a nucleic acid probe is a DNA or RNA oligonucleotide complementary to a sequence in a target gene or RNA; when the probe and the target come together, they hybridize (◀ Section 12.1). Nucleic acid probes can be made fluorescent by attaching fluorescent dyes to them. The fluorescent probes can then be used to identify organisms that contain a nucleic acid sequence complementary to the probe. This technique is called **fluorescence in situ hybridization (FISH)**, and different applications are described here, including methods that target phylogeny (Figure 19.12 and see Figure 19.13) or gene expression (see Figure 19.14).

Phylogenetic FISH stains are fluorescing oligonucleotides complementary in base sequence to sequences in ribosomal RNA (16S or 23S rRNA in *Bacteria* and *Archaea* or 18S or 28S rRNA in eukaryotes, Chapter 13). Phylogenetic stains penetrate cells without lysing them and hybridize with rRNA directly in the ribosomes. The number of

fluorescent probes bound to a cell reflects the number of its ribosomes. As single microbial cells can contain tens of thousands of ribosomes, strong signals can be achieved. And, because ribosomes are scattered throughout the cell in prokaryotic cells, the entire cell becomes fluorescent (Figures 19.11b and 19.12). One limitation of the FISH technique is that slow-growing organisms often have very low numbers of ribosomes and mRNAs, and therefore fluoresce very poorly. However, new staining methods have been developed that measure protein synthesis directly, and provide essential information about the viability and activity of cells in their natural environments, even when growing slowly (see Figure 19.15).

By targeting sites in the rRNA sequence that are variable between different organisms, phylogenetic stains can be designed to be very specific and react with only one species or a handful of related microbial species. Alternatively, by targeting conserved sequences in the rRNA they can be made more general and react with, for example, all cells of a given phylogenetic domain (*Bacteria*, *Archaea*, *Eukarya*) or a given phylum within a domain. Using FISH, an investigator can identify or track a specific organism of interest or an entire domain of interest in a natural sample. For example, if one wished to determine the percentage of a given microbial population that are *Archaea*, an archaeal-specific phylogenetic stain could be used in combination with DAPI (Section 19.4) to assess *Archaea* and total numbers, respectively, and a percentage derived by calculation.

FISH technology can also employ multiple phylogenetic probes at once. With a suite of probes, each designed to react with a particular organism or group and each containing its own fluorescent dye, FISH can image multiple taxa in a habitat in a single experiment (Figure 19.13 and see MicrobiologyNow on page 648). Similarly, the method easily distinguishes between genetically distinct cells of similar morphology (Figure 19.11b). If FISH is combined with confocal microscopy (◀ Section 1.9), it is possible to explore

Figure 19.13 FISH analysis of activated sludge from a wastewater treatment plant. (a) Nitrifying bacteria. Red, ammonia-oxidizing bacteria; green, nitrite-oxidizing bacteria. (b) Confocal laser scanning micrograph of a sewage sludge sample treated with three phylogenetic FISH probes, each containing a fluorescent dye (green, red, or blue) that identifies a particular group of *Proteobacteria* (Chapter 16). Green-, red-, or blue-stained cells reacted with only a single probe; other cells reacted with two (turquoise, yellow, purple) or three (white) probes.

microbial populations with depth, as, for example, in a biofilm (► Section 20.4). In addition to microbial ecology, FISH is also an important tool in the food industry and in clinical diagnostics for the microscopic detection of specific pathogens in food products or clinical specimens.

Single-Cell Metabolic Activity Staining Using CARD-FISH and BONCAT-FISH

FISH methods have been developed for measuring the metabolic activity of single cells by using probes for specific messenger RNAs (transcriptional activity) or for protein synthesis (translational activity). Besides characterizing different taxa in a habitat as phylogenetic stains do, these forms of FISH measure *gene expression*. These microscopic methods thus complement phylogenetic staining—techniques that answer the microbial ecologist’s important question of “Who is there?”—by answering the other important question in microbial ecology: “What are they doing?”

Measuring transcription requires targeting messenger RNA (mRNA), which is much less abundant in cells than rRNA; because of this, standard FISH techniques cannot be applied. Instead, the signal (fluorescence) must be amplified. A FISH method that enhances the signal is called *catalyzed reporter deposition FISH* (CARD-FISH). In CARD-FISH the specific nucleic acid probe contains a molecule of the enzyme peroxidase conjugated to it instead of a fluorescent dye. After there has been time for hybridization between the probe and a specific mRNA, the preparation is treated with a fluorescently labeled compound called *tyramide*, which is a substrate for peroxidase. Within cells containing the nucleic acid probe, the tyramide is converted by the activity of peroxidase into a very reactive intermediate that covalently binds to adjacent proteins; this amplifies the signal sufficiently to be detected by fluorescence microscopy (Figure 19.14). Each molecule of peroxidase activates many molecules of tyramide so that even mRNAs present at very low abundance can be visualized. Besides detecting mRNA, CARD-FISH

is also useful in phylogenetic studies of microbes that may be growing very slowly, such as organisms inhabiting the open oceans where cold temperatures and low nutrient concentrations limit growth rates (Figure 19.14). Because such cells have few ribosomes compared with more actively growing cells, standard FISH methodology often yields only a weak signal.

Although cells that fluoresce brightly by FISH are likely actively synthesizing proteins (as indicated by their high number of ribosomes), a direct measure of translational activity can be made using *bioorthogonal noncanonical amino acid tagging* (BONCAT) combined with FISH (**BONCAT-FISH**). Bioorthogonal compounds are synthetic molecules that mimic natural metabolites and when assimilated and metabolized by a living cell do not interfere with normal physiological processes. Similarly, bioorthogonal analysis refers to a chemical reaction that can occur inside a living cell without interfering with normal function.

In BONCAT (Figure 19.15), cells are first incubated with a modified version of a normal cellular metabolite, such as the amino acid methionine containing a reactive alkyne group (Figure 19.15a). This methionine analog is called a noncanonical (meaning nonstandard) amino acid. Following incorporation of this analog into proteins of actively growing cells, the cells are treated with a fluorescent reporter molecule containing a chemically reactive azide group that bonds specifically to the methionine analog by way of its reactive alkyne group (Figure 19.15b). The phylogenetic identity of translationally active cells is then determined using standard FISH technology in which the rRNA probe is labeled with a different fluorescent dye from that attached to the azide group. An example of BONCAT-FISH to identify translationally active cells in sediments of a marsh estuary is shown in Figure 19.15c. Note that only some of the cell clusters stained green by a bacteria-specific FISH probe are also translationally active, as indicated by BONCAT magenta staining. Thus, both a phylogenetic snapshot and an activity snapshot are obtained in a single experiment.

After BONCAT-FISH, further genetic analysis is possible by using cell sorting to recover labeled cells for genomic analysis of sorted populations or of single cells (see Section 19.12). Once cells have been concentrated by cell sorting techniques, sequencing can be done on single genes, specific gene families, or entire genomes to yield an increasingly more detailed picture of the genetic makeup of the targeted cells.

Although the techniques we have just discussed do not require laboratory culture, in Part III we consider what microbial ecologists typically mean when they say their microbial community analyses are “culture-independent.”

Magenta, translationally active cells stained using BONCAT. The large green ovoid cells are about 4 μm in diameter, the large magenta cells are about 6 μm in diameter, and the small magenta rod-shaped cells are about 1.5 μm long.

III • Culture-Independent Molecular Analyses of Microbial Communities

Revolutionary changes in DNA sequencing technology have made it possible to rapidly recover vast amounts of gene and genome sequence information from the environment. However, fundamental ecological understanding is possible only when that sequence information is paired with appropriate measures of cellular and community activities.

Microbial biodiversity studies often forgo isolating organisms or even quantifying or identifying them microscopically. Instead, complementary molecular methods are used to measure the biodiversity, potential activities, and realized activities of complex communities. As we now review in this section, gene and genome sequencing serve as an important measure of diversity and potential activity, with the caveat that annotation of all novel gene functions remains a daunting challenge (◀ Section 10.2). However, *detection* of a gene is not the same as *gene expression*. As we will discuss in the following two sections, metabolic activity can be measured at the level of both the community and single cells by combining analyses

of gene expression (transcription and translation) with measurements of active processes using the tools of metabolomics (◀ Section 10.10) and isotopic tracers to unravel the food webs sustaining complex microbial communities.

Many surveys of microbial diversity and potential activity are performed at the gene level using the polymerase chain reaction (PCR), DNA fragment analysis by gel electrophoresis (DGGE, T-RFLP, ARISA, each discussed below) or molecular cloning, and DNA sequencing and analysis (Chapters 10 and 12). Increasingly, as a result of changing technologies in DNA sequencing, entire genomes extracted from cells present in an environmental sample are analyzed as a more comprehensive measure of the biodiversity of microbial communities. We begin with an overview of single gene analysis and then introduce **multi-omics**, the integration of data from multiple omics platforms to more fully characterize microbial community structure and function (see Figure 19.21). The term *omics* (Chapter 10) is increasingly used to describe individual or various combinations of genomics, transcriptomics, proteomics, and metabolomics for analysis of organisms and communities of organisms. When these methods are used for the study of complex microbial communities, the terminology is often modified with the prefix “meta” (e.g., *metagenomics*, *metatranscriptomics*, *metaproteomics*) as discussed in Section 19.8.

19.6 PCR Methods of Microbial Community Analysis

We discussed the principle of the polymerase chain reaction (PCR) in Section 12.1. Recall the major steps involved: (1) Two nucleic acid primers are hybridized to a complementary sequence in a target gene; (2) DNA polymerase copies the target gene; and (3) multiple copies of the target gene are made by repeated melting of complementary strands, hybridization of primers, and new synthesis (◀ Figure 12.2). From a single copy of a gene, several million copies can be made for subsequent analyses. PCR finds wide applications in microbial ecology.

PCR and Microbial Community Analysis

Which genes are best suited to be target genes for microbial community analyses? Because genes encoding the small subunit ribosomal (SSU) rRNAs are phylogenetically informative and techniques for their analysis are well developed (◀ Section 13.11), they are widely used in community analyses. Moreover, because rRNA genes are universal and contain several regions of high sequence conservation, it is possible to amplify them from all organisms using only a few different PCR primers, even though the organisms may be phylogenetically distantly related. In addition to rRNA genes, genes that encode enzymes for metabolic functions unique to a specific organism or group of related organisms can be the target genes (Table 19.3). Many of the organisms that harbor these genes are described in Chapter 15.

Genes such as those encoding rRNAs that have retained ancestral function while changing in sequence over time as species have diverged are called *orthologs* (◀ Sections 13.8 and 13.11 and Figure 13.16). Assuming absence of horizontal gene transfer (◀ Section 13.9), organisms that share the same or very closely related orthologous genes

are called a **phylotype**. In microbial ecology, the phylotype concept is primarily used to provide a natural (phylogenetic) framework for describing the microbial diversity of a given habitat, regardless of whether the identified phylotypes are cultured organisms or not. Thus, the word *phylotype* is widely used to describe the microbial diversity of a habitat based solely on nucleic acid sequences. It is only when additional physiological and genetic information becomes available, typically after the organism is brought into laboratory culture (Sections 19.2 and 19.3), that proposing a genus and species name for a phylotype becomes possible.

In a typical molecular community analysis experiment, total DNA is isolated from a microbial habitat (Figure 19.16). Commercially

Figure 19.16 Steps in single-gene biodiversity analysis of a microbial community. From total community DNA, 16S rRNA genes are amplified using primers that target only *Firmicutes*, a group of gram-positive *Bacteria* that includes the endospore-forming genera *Bacillus* and *Clostridium*. The 16S rRNA gene products obtained from PCR are then either separated by DGGE or sequenced directly by next-generation sequencing; from the sequence data, a phylogenetic tree is generated. “Env” indicates an environmental sequence (phylotype). Alternatively, in T-RFLP analyses, the PCR-amplified products are labeled with a fluorescent dye and fragmented by cutting with a restriction enzyme before electrophoresis. The number of peaks identified by fluorescence corresponds to the number of phylotypes.

available kits that yield high-purity DNA from soil or other complex habitats are available for this purpose. The DNA obtained is a mixture of genomic DNA from all of the microorganisms that were in the sample from the habitat (see Figure 19.17). From this mixture, PCR is used to amplify the target gene and make multiple copies of each variant (phylotype) of the target gene. If RNA is isolated instead of DNA (to detect those genes being transcribed), the RNA can be converted into complementary DNA (cDNA) by the enzyme reverse transcriptase (◀ Section 11.11) and the cDNA subjected to PCR as for isolated DNA. However, regardless of whether DNA or RNA is originally isolated, the different phylotypes need to be sorted out following the PCR step before they can be sequenced. Sorting can be accomplished using one of three different methods: (1) physical separation by gel electrophoresis (◀ Section 12.2), (2) clone library construction (◀ Sections 12.2 and 12.9), and (3) next-generation sequencing technology (◀ Section 10.2). We consider these methods now.

Denaturing Gradient Gel Electrophoresis: Separating Very Similar Genes

One method to resolve phylotypes is **denaturing gradient gel electrophoresis (DGGE)**, which separates genes of the same size that differ in their melting (denaturing) profile because of differences in their *base sequence* (Figure 19.17a, b). DGGE employs a gradient of a DNA denaturant, typically a mixture of urea and formamide. When a double-stranded DNA fragment moving through the gel reaches a region containing sufficient denaturant, the strands begin to “melt”; at this point, their migration stops (Figure 19.17b, c). Differences in base sequence cause differences in the melting properties of DNA. Thus, the different bands observed in a DGGE gel are

phylotypes that can differ in base sequence significantly or by as little as a single base change.

Once DGGE has been performed, the individual bands are excised and sequenced (Figure 19.17). With 16S rRNA as the target gene, for example, the DGGE pattern immediately reveals the number of phylotypes (distinct 16S rRNA genes) present in a habitat (Figure 19.17c). Although not suited for the analysis of highly complex communities, since individual bands may not be fully resolved, the method provides an excellent mechanism to quickly evaluate temporal and spatial shifts in microbial community structure (Figure 19.17c). If PCR primers specific for genes other than 16S rRNA are used, such as a metabolic gene (Table 19.3), the variants of this specific gene that exist in the sample can also be assessed. Thus, although the number of bands on a DGGE gel is an overview of the biodiversity in a habitat (Figure 19.17c), sequence analysis is still required for identification and to infer phylogenetic relationship.

T-RFLP and ARISA

A rapid method of microbial community analysis is *terminal restriction fragment length polymorphism (T-RFLP)*. In this method a target gene (usually an rRNA gene) is amplified by PCR from community DNA using a primer set in which one of the primers is end-labeled with a fluorescent dye. The PCR products are then treated with a restriction enzyme (◀ Section 12.2) that cuts the DNA at specific sequences. This generates a series of DNA fragments of varying length, the number of which depends on how many restriction cut sites exist in the DNA. The fluorescently labeled terminal fragments are then separated by size on an automated DNA sequencing instrument that detects fluorescent fragments (thus, only the terminal dye-labeled fragments are detected). The pattern obtained shows the

Figure 19.17 PCR and DGGE gels. Bulk DNA was isolated from a microbial community and amplified by PCR using primers for 16S rRNA genes of *Bacteria* (a, lanes 1 and 8). Six bands later resolved by DGGE (b, lanes 2–7) were excised and reamplified and each gave a single band at the same location on the PCR gel (a, lanes 2–7). However, by DGGE analysis, each band migrated to a different location on the gel (b, lanes 2–7). Note that all bands migrate to the same location in the nondenaturing PCR gel because they are all of the same size, but they migrate to different locations on the DGGE gel because they have different sequences. (c) DGGE profiles of microbial communities from different wastewater treatment facilities amplified using primers for the 16S rRNA genes of *Bacteria*.

rRNA sequence variation and general abundance of different sequence types (fragment fluorescence intensity) in the microbial community sampled (Figure 19.16).

DGGE and T-RFLP both measure *single-gene diversity*, but in different ways. The pattern of bands on a DGGE gel reflects the number of same-length sequence variants of a single gene (Figure 19.17), whereas the pattern of bands on a T-RFLP gel reflects variants differing in DNA sequence of a single gene as measured by differences in restriction enzyme cut sites. The information obtained from a T-RFLP analysis, in addition to providing insight into the diversity and population abundances of a microbial community, can also be used to infer phylogeny. Diagnostic information for each fragment includes knowledge of sequences near both ends (primer sequence and restriction enzyme cut site), knowledge that a second restriction site does not exist within the fragment, and fragment length. Using specialized software, this information can be used to search for matching 16S rRNA sequences in public databases. Although this is of some predictive value, closely related sequences are often not differentiated by these criteria. Thus, T-RFLP generally underestimates the diversity within a microbial community.

A technique related to T-RFLP that provides more detailed analysis of microbial communities is *automated ribosomal intergenic spacer analysis* (ARISA), which exploits the typical proximity of 16S and 23S rRNA genes in the genomes of *Bacteria* and *Archaea*. The DNA separating these two genes, called the *internal transcribed spacer* (ITS) region, differs in length among species and often also differs in length among the multiple rRNA operons of a single species (Figure 19.18a). The PCR primers for ARISA are complementary to conserved sequences in the 16S and 23S rRNA genes that flank the spacer region. Amplification (Figure 19.18b) and analysis (Figure 19.18c) are conducted as described for T-RFLP, resulting in a complex pattern of bands that can be used for community analysis. However, ARISA differs from T-RFLP in that ARISA does not require a restriction enzyme digestion following PCR amplification. The word “automated” in the ARISA acronym refers to the use of a DNA sequencing instrument that automatically identifies and assigns sizes to each dye-labeled fragment (Figure 19.18c), as can also be done in T-RFLP analyses. ARISA has received greatest application in the study of microbial community dynamics by monitoring, for example, changes in the presence and relative abundance of a specific community member through time and space.

Figure 19.18 Automated ribosomal intergenic spacer analysis (ARISA). (a) Structure of rRNA operon spanning the 16S rRNA gene (positions 1–1540), an internal transcribed spacer (ITS) region of variable length, and the 23S rRNA gene (positions 1–2900). The PCR primers, one labeled with a fluorescent dye, are complementary to conserved sequences near the ITS region. (b) Amplified DNA fragments of different lengths, each corresponding to a community member. (c) Fragment analysis determined by an automated DNA sequencer. The peaks, which correspond to different ITS regions, can be identified by cloning and sequencing the amplified products.

Diversity Studies Using Clone Libraries or Next-Generation Sequencing

Early molecular microbial diversity research relied on the construction of clone libraries to separate individual amplified DNA molecules (*amplicons*); each clone in the library contained a unique sequence that was then used as a template for sequence determination (◀ Sections 10.2 and 12.2). Figure 19.17a shows that a 16S rRNA gene amplicon mixture appears as a single band when run on a nondenaturing gel. However, because the amplified target gene came from a *mixture* of different cells, the different phylotypes in the single band have different sequences and need to be sorted out before they are sequenced. Today this is almost exclusively done by next-generation sequencing systems (◀ Section 10.2) rather than by DGGE or by cloning. There are many such sequencing platforms available (Figure 19.19), and each has advantages and disadvantages. Long sequence reads are particularly useful for environmental metagenomic studies where the goal is to reconstruct genomes from members of the microbial community (Section 19.8). The MinION (nanopore technology, ◀ Explore the Microbial World, “DNA Sequencing in the Palm of Your Hand,” Chapter 10) sequencing system is widely useful for this purpose because it can generate the long sequence reads necessary for genome assembly purposes. Once a genome is assembled, sequence accuracy can be improved using other platforms better capable of sequencing short DNA fragments at high fidelity (Figure 19.19a).

MinION and these other next-generation sequencing systems do not require a cloning step, as individual DNA fragments are separated and amplified on the sequencing device itself; thus, PCR products can be used directly for sequencing. Since millions of amplification reactions are then conducted simultaneously, the total number of sequencing reads vastly exceeds what is possible by sequencing individual clones obtained in a clone library one at a time (Figure 19.19). This tremendous volume of sequence data allows for what has been called *deep sequence analyses*, meaning that minor phylotypes that were possibly missed by the more limited and expensive clone library method are now revealed (Figure 19.19b). For example, if a particular phylotype were present at only 0.01% in a library of cloned sequences, sequencing of a thousand clones or more would be needed to ever detect it. By contrast, next-generation sequencing would detect this low-abundance phylotype along with its more abundant neighbors. This collection of minor phylotypes, which represent a substantial fraction of total diversity but only a minor component of total organism abundance in most environments, has been called the *rare biosphere* (Figure 19.19). Once next-generation sequencing reveals these rare but potentially very important components of a microbial community, various tools in the microbial ecologist’s toolbox can be deployed to learn more about their activities and overall role in their ecosystem.

Results of PCR Phylogenetic Analyses

Phylogenetic analyses of microbial communities have yielded surprising results. For example, using the gene encoding 16S rRNA as the target, analyses of natural microbial communities typically show that many phylogenetically distinct *Bacteria* and *Archaea* (phylotypes) are present whose rRNA gene sequences differ from those of all known laboratory cultures. Moreover, using quantitative PCR (qPCR, a

Figure 19.19 Community diversity analyses using next-generation sequencing technology. (a) Current sequencing platforms (◀ Section 10.2) have the capacity to generate 10^{12} nucleotides (nt) of sequence in a single sequencing run (requiring a week or less), with individual read lengths varying from 100 to 800 nucleotides. The two segments in the rightmost bar show that technologies generating longer reads have lower throughput per sequencing run. (b) This enormous sequencing capacity revealed many unique phylotypes that were not detected using DGGE or clone library sequencing. Fewer than 100 unique phylotypes would be detected by Sanger (first-generation) sequencing of 1000 clones in a library of 16S rRNA gene PCR amplicons. Jed Fuhrman is acknowledged for input to part b.

variant of PCR that allows each phylotype to be quantified as well as amplified, ◀ Section 12.1), it has often been observed that the most abundant phylotypes in a natural microbial community are ones that have thus far defied laboratory culture. These sobering results make it clear that our knowledge of microbial diversity from enrichment cultures is far from complete and that enrichment bias (Section 19.1) is a serious problem in culture-dependent biodiversity studies. Obviously, much work remains to put our abilities to culture microbes on a par with our existing abilities to detect and identify them in nature.

- How has next-generation sequencing technology altered our understanding of microbial community diversity?

19.7 Microarrays for Analysis of Microbial Phylogenetic and Functional Diversity

We previously considered the use of DNA chips—a type of *microarray*—for assessing overall gene expression in a microbial pure culture (◀ Section 10.8). Specific microarrays can also be constructed for rapid gene-based analyses of biodiversity and the functional potential of natural microbial communities. Microarrays designed to exclusively target different 16S rRNA sequence types (phylotypes), called *PhyloChips*, have been used in the past, but microarrays employed for environmental studies now focus on metabolic genes of biogeochemical significance. This type of microarray, the *GeoChip*, detects genes required for selected metabolic processes, including sulfate reduction, ammonia oxidation, denitrification, and nitrogen fixation (Figure 19.20 and Table 19.3).

The GeoChip—also called a *functional gene microarray*—targets genes that function in a measurable environmental process. However, because genes encoding enzymes of similar function can vary significantly in sequence, the arrays must contain many thousands of probes in order to achieve reasonable coverage of natural diversity. Even then, such arrays may only sample a fraction of the actual functional diversity in a habitat. Successful use of a GeoChip requires several steps: (1) isolation of total community DNA from the sample, (2) random sequence amplification (as is also used for amplification of DNA from a single cell, ◀ Section 10.11), (3) fluorescence labeling of the environmental DNA, and (4) hybridizing the environmental DNA to probes on the GeoChip. The GeoChip functional gene microarray contains over 160,000 probes covering more than 1400 gene families encoding proteins that participate in carbon, nitrogen, and sulfur cycling processes. By measuring the hybridization signal conferred by binding of environmentally derived DNA to each probe on the microarray (Figure 19.20), a rapid appraisal of the potential metabolisms operating in a particular habitat can be obtained.

GeoChips circumvent many of the time-consuming steps of molecular microbial ecology—PCR, DGGE, cloning, and sequencing (Figure 19.16). In addition, the GeoChip is useful for detecting low-abundance genes that would be difficult to identify by sequencing and also offers some information on actual gene abundance. However, an important caveat to the use of microarrays is the possibility

Functional category	Gene families	Total probes	Database gene coverage (%)
Carbon cycling	149	26922	49
Nitrogen cycling	32	6493	52
Sulfur cycling	27	4739	64
Phosphorus	7	3260	52

TOTAL	1447	161,961	44

(b)

Figure 19.20 GeoChip analysis of functional gene diversity. The GeoChip contains over 161,000 probes covering more than 365,000 gene sequences in public databases, encompassing most major biogeochemical processes. The image shows green fluorescence of varying intensity (approximating gene abundance) following hybridization of fluorescent dye-labeled environmental DNA to the individual probes in one region of the high-density array of probes. The red spots correspond to repeated applications of a known amount of a reference DNA standard. A red-dye-labeled probe complementary to the reference standard was added to the environmental DNA prior to hybridization. Red fluorescence of equal intensity among the reference standard spots confirms that hybridization was uniform throughout the array.

of *nonspecific hybridization*. That is, gene variants that are closely related in sequence may not be resolved in a microarray because of overlapping hybridization patterns. Moreover, totally unrelated genes may yield false positive results if they are sufficiently complementary in base sequence to hybridize to the probe. And finally, unlike nucleic acid sequencing, whose costs keep plummeting yearly, designing and manufacturing gene chips are not yet inexpensive endeavors. Combined with culture-independent phylogenetic diversity studies (Section 19.6), functional gene arrays offer the microbial ecologist a detailed picture of both the diversity of organisms and the diversity of metabolisms in any given environment. However, what the GeoChip and related functional gene arrays *do not* reveal is actual metabolic activity; they show only the *genetic potential* for metabolic activity. We got a taste of how metabolic activity can be measured using BONCAT, a microscopic method of detecting metabolic activity (Figure 19.15). In the next section, we explore other methods of assessing microbial activity that use omics, the most powerful tools in the microbial ecologist's toolbox.

- What are the advantages and disadvantages of microarray technology compared to sequencing PCR products?

19.8 Environmental Multi-omics: Integration of Genomics, Transcriptomics, Proteomics, and Metabolomics

As was presented in Chapter 10, a more complete understanding of how a microorganism functions requires an integrated accounting of all central cellular processes. These include gene expression, functional knowledge of all gene products and product activities, and all metabolites produced during growth. The analytical tools used to characterize those processes in pure cultures (◀ Sections 10.11–10.13) are now being applied to the study of complex microbial communities to yield an unprecedented view of microbial ecology.

Characterization of a natural system is a much more complex problem than the analysis of a single organism. Not only must processes of each organism be measured, but the many changing biotic and abiotic interactions that modify those processes must also be resolved. Here we consider the methods of genomic, transcriptomic, proteomic, and metabolomic analysis required to unveil patterns of microbial diversity that will ultimately lead to a more predictive understanding of microbial community function and response to environmental change. Collectively called omics or, when used in combination, *multi-omics*, these rapidly evolving methods are having a dramatic impact on our understanding of the structure and function of natural microbial communities. We begin with an overview of individual omics (Figure 19.21), and then present exemplar case studies of their application.

Figure 19.21 Multi-omics methods overview. The combined use of advanced genetic, molecular, microscopic, and isotopic methods is revolutionizing the study of natural microbial communities. Assignment of protein and transcript sequences to specific community members is accomplished by mapping their sequences on unique genomes assembled from metagenomic sequences. Abbreviations: FISH, fluorescence in situ hybridization (Figures 19.11–19.14); BONCAT, bioorthogonal noncanonical amino acid tagging (Figure 19.15); FACS, fluorescence-activated cell sorting (see Figure 19.42); MAR, microautoradiography (see Figure 19.41); SIMS, secondary ion mass spectrometry (see Figure 19.39).

Metagenomics and Reconstructing Environmental Genomes

An encompassing approach to the genetic characterization of microbial communities is **environmental genomics**, also called **metagenomics**. Before the metagenomics era, microbial community analyses typically focused on the diversity of a *single* gene in an environmental sample. By contrast, in environmental genomics, *all* genes in a given microbial community can be sampled and, if the experiment is properly designed, the information obtained can support a much deeper understanding of the structure and function of the community than can single-gene analyses.

The goal of a metagenomics study today is to use next-generation DNA sequencing (◀ Section 10.2) to identify as many genes as possible from an environmental DNA sample and determine the phylogeny of the organism(s) to which the genes belong. Although complete and finished genomes are often not the goal of metagenomics, there is increasing interest in assembling individual genomes from large metagenomic datasets to at least the draft stage. Rather than simply generating a list of all genes present in an environment, nearly complete genomes can better connect functional and phylogenetic aspects of a microbial habitat. An example of this is shown in the “connection graph” of Figure 19.22 that depicts an assembly of genomes from a coastal marine water sample. A total of 58.5 *billion* nucleotides in the metagenome were used to stitch together these complete and near-complete genomes. Such massive metagenomic undertakings can be highly complex enterprises but often reveal links between physiologies and phylogenies not obtainable in the absence of reconstructed genomes.

Figure 19.22 Genome assembly from a coastal marine metagenome consisting of 58.5 billion nucleotides of sequence. This “connection graph” is intended as a visual representation of the complexity and abundance of partial and complete genomes assembled from the water sample. The long strands, colored by differences in the percentage of guanine plus cytosine content, correspond to prokaryotic genomes and the small circular strands are most likely from viruses or plasmids.

Vaughn Iverson and Ginger Armbrust

Figure 19.23 Single-gene versus environmental genomic approaches to microbial community analysis. In the environmental genomic approach, all community DNA is sequenced, but the assembled genomes may not all be complete. Total gene recovery is variable and depends on several factors including the complexity of the habitat and the amount of sequence determined. Recovery is typically better when diversity is low and sequence redundancy is high.

A problem with genome assembly from a mixture of environmental DNA sequence reads, however, is that the genomes obtained are unlikely to be either complete or clonal, instead being composed of fragments of DNA from closely related strains of a species (Figure 19.23). This has proven to be a major problem in the assembly of soil microbial genomes, for example, from large pools of metagenomic data. A single gram of fertile soil contains about 10^{12} bacterial and archaeal genes and 10^9 genomes; complete coverage of these genes is not yet feasible with available technology, even with the sequencing of 300 billion nucleotides in one soil study! Single-cell genomics (◀ Section 10.11 and Figure 10.30) may ultimately overcome this problem (see also Section 19.12), but by definition, this method only provides information from a single microbial cell.

Of critical importance in evaluating a genome reconstructed from metagenomic DNA is to assess whether it contains all of the genes required by a cell (for example, all necessary tRNA and rRNA genes and genes encoding essential proteins such as DNA and RNA polymerases) and is therefore a legitimate genome candidate. In addition, an assessment of the relative abundance of genes encoding specific functions is equally valuable, since abundance changes suggest interactions among species or a common response to a particular environmental variable. For example, if a high number of genes were recovered in the pathway for nitrogen fixation, this would

suggest that the environment sampled was limited in NH_4^+ , NO_3^- , and other forms of fixed nitrogen, thus selecting for nitrogen-fixing bacteria. Figure 19.23 contrasts the environmental genomic approach with single-gene analysis of microbial communities.

Although metagenomics can reveal much about a microbial habitat, there are many things metagenomics cannot tell us about environmental microbial communities. Currently no methods are available for translating metagenomic sequence data into fundamental physiological information about the microbial community, such as the maximum specific growth rate of different species, their affinities for nutrients, their optimum, minimum, and maximum pH or temperature for growth, or their speed of recovery from starvation. Moreover, any metabolisms never before encountered are unlikely to be deduced from nucleotide sequence data alone. These realities once again underscore why it is important to culture new microbes from nature; at present, there is simply no substitute for culture-based characterization to define many critical aspects of a microbe's functional biology.

Some Examples of Environmental Genomics

Environmental genomics can detect both new genes in known organisms and known genes in new organisms. A large number of interesting microbial communities have been probed using early metagenomic tools. In an early study of bacterial and archaeal diversity in the Sargasso Sea (a low-nutrient region of the Atlantic Ocean near Bermuda), over one billion nucleotides were sequenced and from this over 1800 bacterial and archaeal species were detected, including 148 previously unknown phylotypes and many novel genes. Many of these species had previously been missed using rRNA community analyses that employed PCR and cloning or PCR and DGGE (Section 19.6). Genes that fail to amplify, of course, remain undetected in community analyses, and cloning efficiency is far from 100%. Metagenomics sidesteps these problems by sequencing

DNA directly without the need to amplify it or resolve different phylotypes before sequencing.

The Sargasso Sea metagenome study revealed several novel findings such as the presence of candidate ammonia-oxidizing genes in archaeal genomes, a result that was later confirmed with the isolation and description of a new group of *Archaea*, the *Thaumarchaeota* (◀ Section 17.5). Moreover, genes encoding *proteorhodopsin*, a light-sensitive proton pump present in certain *Proteobacteria* and related to bacteriorhodopsin of extreme halophiles (◀ Section 17.1), were found in the genomes of several new phylogenetic lineages of *Bacteria*. However, despite this major sequencing undertaking, much was missed. This is because 1 milliliter of seawater contains approximately 5 *trillion* base pairs (bp) of bacterial genomic DNA and would therefore require 5000 times the sequencing effort just to cover each base pair once on average! Hence, even with current technology (see Table 10.2)—which can generate over a trillion bp of sequence in a few days (Figure 19.19)—no one natural environment has yet been sequenced completely.

Genomic/metagenomic approaches have also revealed variations in genes associated with a single phylotype; that is, in strains that contain identical, or nearly identical, rRNA genes. For example, in studies of *Prochlorococcus*, the most abundant cyanobacterium (oxygenic phototroph) in the ocean (▶ Section 20.11), comparison of the genome sequences of cultured strains with *Prochlorococcus* genes obtained from metagenomic analyses of ocean water identified extensive regions shared between the cultured and environmental populations (Figure 19.24). This high level of gene conservation confirms that the organisms in culture are typical of environmental populations. In addition, however, these analyses also identified several highly variable regions in which the genomes of cultured strains differed significantly from those of environmental populations. These variable regions were clustered in the genome as *genomic islands* (chromosomal islands, ▶ Section 13.10), and likely encode

Figure 19.24 Metagenomic analysis. Sequences (represented as green dashes) from the Sargasso Sea metagenome that align to the genome sequence of a cultured *Prochlorococcus*, showing regions where the cultured strain has genes of high similarity (high percent identity) with sequences in the metagenome, and other regions (shaded) where it lacks genes in common (genomic islands, ISL1–ISL5). Since the DNA sequence contained within the genomic islands is thought to encode niche-specific functions, the cultured strain would likely not exhibit the same environmental distribution as strains containing all the island genes. Fold coverage is a measure of how completely the various regions in the *Prochlorococcus* genome are accounted for by similar sequences in the metagenome.

functions that control the growth response of particular *Prochlorococcus* populations to environmental variables unique to their habitat, such as temperature or light quality and intensity (► Section 20.11 and Figure 20.26).

Metatranscriptomics, Metaproteomics, and Metabolomics

As we discussed in Chapter 10, the genomics era has spawned several additional “omics,” in particular, *metatranscriptomics*, *metaproteomics*, and *metabolomics*. **Metatranscriptomics** is analogous to metagenomics but analyzes the sequences of community RNA rather than community DNA. The isolated RNA is converted into cDNA by reverse transcription (◀ Section 11.11) before sequencing and analysis as for DNA. Whereas metagenomics describes the functional capacities of the community (for example, the relative abundance of specific genes), metatranscriptomics reveals which

genes in the community *are actually being expressed* and the relative level of that expression, at a specific time and place (Figure 19.21). Because the expression of most genes in *Bacteria* and *Archaea* is controlled at the level of transcription (Chapter 7), mRNA abundance can be taken as a census of individual gene expression levels. Thus, gene transcript abundance determined for an entire community can be used to infer the operation of major metabolic processes catalyzed by that community at the time of sampling (Figure 19.25).

Metaproteomics, the measure of the diversity and abundance of different *proteins* in a community, is an even more direct measure of cell function than is metatranscriptomics. This is because different mRNAs have different half-lives and efficiencies of translation, and thus will not all yield the same number of protein copies. However, metaproteomics is a greater technical challenge than either metagenomics or metatranscriptomics. Protein identification, usually by

Figure 19.25 Metatranscriptomic analysis of coastal marine surface waters. Expression of genes for key steps in the N and P cycle in a seawater sample determined by sequencing environmental mRNA. These data showed that the microbial community was using both inorganic (high expression of P transporters) and organic (alkaline phosphatase) forms of phosphate (PO_4^{3-}). Low levels of transcripts for genes required for nitrate (NO_3^-) assimilation contrasted with the high expression of genes for ammonia (NH_3) transport and chemolithotrophic NH_3 oxidation. Also, as expected for oxic marine surface waters, there was little expression of genes for NO_3^- respiration. Data courtesy of Mary Ann Moran, University of Georgia Marine Sciences.

mass spectrometric characterization of peptides released from enzymatic digestion of the total protein pool by specific proteases (◀ Section 10.9), relies on naturally available material since it is not possible to amplify protein sequences as one does using PCR to amplify nucleic acids for sequencing. Protein identification also requires at least partial separation of the individual peptides in order to reduce complexity of the sample and a reference genome or metagenome to identify potential coding sequences (see Figure 19.21). **Metabolomics** is the comprehensive analysis of cellular and extracellular metabolites (also called **exometabolites**) of a microbial community and is the most direct measure of the food web structure of a community. As discussed in Chapter 10 (◀ Section 10.10), advanced methods in mass spectrometry are now providing the analytical power required to resolve and quantify the many hundreds of metabolites that form the food webs of natural microbial communities.

The utility and power of integrating omics methods for the study of natural microbial communities has been on display in many ecological studies published in the scientific literature in recent years and was evident in the metatranscriptomic study shown in Figure 19.25. We continue this theme here with two case studies, one employing metaproteomics and the other metabolomics.

Utility of Metaproteomics: An Environmental Case Study of Permafrost

Permafrost covers an estimated 20% of the land on Earth and sequesters large amounts of organic carbon. Because climate change will likely lead to the release of two major “greenhouse gases”—CO₂ and CH₄—from permafrost, identifying the microbes inhabiting actively melting permafrost along with their metabolic potential is essential for climate predictions. Using a combination of metagenomics (◀ Section 10.7) and metaproteomics (◀ Section 10.9), a revealing snapshot of the genes and proteins of the microbial community present in a permafrost meltwater bog has been obtained (Figure 19.26).

During the metagenomic analysis of the bog, DNA sequences were assembled and annotated into complete and partial genomes (Figure 19.26a). This analysis indicated that *Bacteria* of the phyla *Proteobacteria*, *Actinobacteria*, and *Chloroflexi* predominated (Chapters 15 and 16), while methanogens (*Euryarchaeota*) were the dominant *Archaea* (Chapter 17). From the large amount of sequence data obtained, the genomes of three novel (and as yet uncultured) methanogens could be assembled without any cultures of the organisms having been obtained. This indicated that unique methanogens resided in the permafrost—most likely species that function well in the cold (psychrophiles)—and therefore that the potential for increasing rates of methanogenesis as the permafrost melted was high. Using the annotated DNA sequences and the output from the mass spectrometry detection of peptides, the identity of proteins extracted from the bog sample was determined along with their microbial sources (Figure 19.26b). The proteomics detected an abundance of functionally diverse proteins including those that participate in cellular housekeeping, transport, and organic carbon respiration. But importantly, and in agreement with the metagenomics data, several proteins associated with C₁ metabolism, including those necessary for both making methane (methanogenesis,

◀ Section 14.15) and oxidizing methane (methanotrophy, ▶ Section 14.16) as well as oxidizing and reducing carbon monoxide (CO dehydrogenases), were also detected in the bog microbial community.

This combined metagenomic and metaproteomic snapshot of a major microbial community highlights the power of omics for resolving the “who” and “how” of complex microbial communities and for using the results to predict the response(s) of these communities to environmental changes. In the case of permafrost melting, the potential for the release of large amounts of CO₂ (due to increased respiration of organic carbon) and CH₄ (due to increased activities of methanogens) from permafrost as climate change progresses (see Section 21.9) was clearly apparent (Figure 19.26).

Utility of Metabolomics: An Environmental Case Study of Biocrusts

A study of the microbial ecology of biological soil crusts (biocrusts) offers an example of how metabolomics can provide new understanding of food webs that sustain natural microbial communities. Biocrusts are microbe-dominated communities that develop in arid environments of limited vegetation that in part function to reduce soil erosion (Figure 19.27; ▶ Section 20.6). They are relatively simple communities in which a dominant filamentous cyanobacterium, in this case *Microcoleus vaginatus* (a member of the *Oscillatoriales*, ▶ Section 15.3), is the primary producer and the ultimate source of dissolved carbon used by associated heterotrophic microbes. These communities persist in a desiccated, dormant state for extended periods but rapidly become active after a rainfall. Analysis of the biocrust metabolome using advanced methods of mass spectrometry identified and quantified hundreds of metabolites (e.g., adenine, aspartate, uracil, methylguanine, 2-isopropylmalate, methionine, guanidinobutanoate, glycine betaine, malate, succinate). Many of these metabolites are produced by *Microcoleus* and released to the environment for consumption by other members of the soil crust community. Since this cyanobacterium is unable to fix nitrogen, its nitrogen requirement is largely supplied by nitrogen-containing metabolites supplied by heterotrophic members of the community.

Characterization of the intracellular metabolites and exometabolites of a pure culture of *Microcoleus* showed that a significant fraction of its intracellular metabolites were released during growth and thus made available to heterotrophic community members as exometabolites (Figure 19.28a). In turn, the heterotrophic community produced metabolites used selectively by the *Microcoleus* or by other heterotrophs (Figure 19.28b). Bacterial cultures isolated from the crust were found to have strong substrate preferences, each depleting a certain fraction of the metabolites while ignoring others. There was also little overlap in utilization; only two metabolites, glutamate and a second, unidentified compound, were used by all members of a group of bacterial isolates. Thus, each isolate from the biocrust likely occupies a specialized nutritional niche, using only a subset of the total pool of metabolites as nutrients. Analysis of the patterns of metabolite uptake and release suggested 80 potential cross-feeding patterns. In addition to providing an example of the power of metabolomics for untangling complex food

(a) The thin desert biocrust is stabilized by the filamentous cyanobacterium *Microcoleus*, which binds together soil particles and reduces erosion. (b, c) Visible *Microcoleus* filaments (arrows) show the fine architecture of the crust. *Microcoleus* nourishes a rich community of primarily heterotrophic bacteria, releasing metabolites consumed by community members, which in turn produce metabolites consumed by the cyanobacterium. Environmental metabolomics (see Figure 19.28) has the power to unravel the complex food web that sustains these critical microbial communities in arid lands.

webs, the use of this exometabolomic approach for identifying metabolites used by uncultured community members yields a second scientific benefit: It can guide researchers in formulating selective culture media for enrichment of heterotrophic bacteria that eluded initial cultivation efforts.

In the final part of this chapter, up next, we look at some other tools in the microbial ecologist's toolbox that can measure total microbial community activities.

Check Your Understanding

- What is a metaproteome, and how does it differ from a metagenome and from a metatranscriptome?
- How do environmental multi-omics approaches differ from environmental genomics or single-gene analyses, such as that based on 16S rRNA gene analysis for microbial community characterization?
- How can the most metabolically active cell populations in a community be identified using environmental omics methods?

Figure 19.28 Metabolic network supporting the desert biocrust microbial community. IV • Measuring Microbial Activities in Nature

Microbial communities manifest their presence through the concerted activities of individual microorganisms that together drive major biogeochemical processes. A powerful suite of isotopic and genetic methods combined with high-resolution microscopy and sensor technology have made it possible for the microbial ecologist to map these processes from the level of individual cells to entire environmental systems.

We wrap up this chapter by considering methods for measuring microbial activities in natural samples beyond those already discussed in Parts II and III. The techniques we consider here include the use of radioisotopes, microsensors, nanosensors, stable isotopes, and genomic methods. Activity measurements in a natural sample are *collective* estimates of the physiological reactions occurring in the entire microbial community, although several techniques to be discussed later (Sections 19.10–19.12) allow for a more targeted assessment of physiological activity. Activity measurements reveal both the types and rates of the major metabolic reactions occurring in a habitat, and the various techniques can be used alone or in combination in microbial community analyses. In conjunction with multi-omics analyses, these methods help define the structure and function of microbial ecosystems—the ultimate goal of microbial ecology—and often inform the design of enrichment cultures to bring microbial community members into the laboratory.

19.9 Chemical Assays, Radioisotopic Methods, Microsensors, and Nanosensors

In many studies, direct chemical measurements of microbial reactions are sufficient for assessing microbial activity in an environment. For example, the fate of lactate oxidation by sulfate-reducing bacteria in a sediment sample can be tracked easily. If sulfate-reducing bacteria are present and active in a sediment sample, then lactate added to the sediment will be consumed and SO_4^{2-} will be reduced to hydrogen sulfide (H_2S). Since lactate, SO_4^{2-} , and H_2S can all be measured specifically and with high sensitivity by chemical assay, the transformations of these substances relative to one another in a sample can easily be followed (Figure 19.29a). However, when very high sensitivity is required, or when turnover rates need to be determined, *radioisotopes* are more useful than strictly chemical assays.

Another approach to the sensitive measurement of certain microbial process rates takes advantage of selective chemical inhibition of an enzyme specific to the process. For example, a widely employed chemical inhibitor uses acetylene to inhibit some processes, such as nitrification, or as an alternative substrate in another, such as nitrogen fixation. The final set of tools we will describe in this section are different types of microsensors and nanosensors used to measure an active microbial process by quantifying changes in the concentration of specific chemicals in time and space.

Radioisotopes

When very high sensitivity is required, or turnover rates need to be determined, or the fate of portions of a molecule needs to be

followed, *radioisotopes* are more useful than strictly chemical assays. For instance, if measuring photoautotrophy is the goal, the light-dependent uptake of radioactive carbon dioxide ($^{14}\text{CO}_2$) into microbial cells can be measured (Figure 19.29b). If sulfate reduction is of interest, the rate of conversion of $^{35}\text{SO}_4^{2-}$ to H_2^{35}S can be assessed (Figure 19.29c). Heterotrophic activities can be measured by tracking the release of $^{14}\text{CO}_2$ from ^{14}C -labeled organic compounds (Figure 19.29d), and so on.

Both isotopic and chemical methods are widely used in microbial ecology. To be valid, however, these must employ proper controls because some isotopic transformations might be due to abiotic processes. The *killed cell control* is an essential control in such experiments. That is, it is essential to show that the transformation being measured stops when chemical agents or heat treatments that kill microorganisms are applied to the sample. Formalin at a final concentration of 4% is commonly used as a chemical sterilant in microbial ecology studies. This kills all cells, and transformations that are insensitive to the presence of 4% formalin can be ascribed to abiotic processes (Figure 19.29a). Additional controls are also necessary. For example, if H_2 -driven sulfate reduction is to be measured in a bottle, an essential control is to have a separate bottle identical in every way except that it lacks H_2 (Figure 19.29c). If photosynthesis is to be measured, a dark control is essential (Figure 19.29b), and so on. The art of doing good experimental science is in designing experiments with the correct controls, and this is especially true of bulk assays of microbial activity where particular subsets of the entire microbial community are targeted.

Acetylene as an Inhibitor and an Alternative Substrate

In some activity measurements, it is useful to inhibit the activities of certain organisms in order to focus on the activities of others. For example, the short-chain hydrocarbon acetylene ($\text{HC}\equiv\text{CH}$) is an inhibitor of several metabolisms, including nitrification (◀ Section 14.9), denitrification (◀ Section 14.11), and methanogenesis (◀ Section 14.15). In nitrification, acetylene inhibits the first step, ammonia oxidation to nitrite, while in denitrification, acetylene inhibits the terminal step, the reduction of nitrous oxide (N_2O) to N_2 . Thus, acetylene can be used to focus on particular steps in these processes with the knowledge that the inhibited steps are not occurring. For example, the use of acetylene to block reduction of N_2O is a common assay for denitrification, using the production rate of N_2O (an easily assayed gas) in the presence of acetylene as a measure of the denitrification rate in an environmental sample. Acetylene and other metabolic inhibitors are useful in microbial ecology but must be used with the caveat that the inhibitor might also affect some unrecognized metabolic process that contributes to the activity being measured.

Acetylene is also commonly used for another purpose. The capacity for nitrogen fixation is widely distributed among *Bacteria* and *Archaea* (Table 19.4; ▶ Section 3.12). Nitrogenases are not specific for N_2 and also reduce other triply bonded compounds, such as acetylene, as alternative substrates. Unlike the reduction of N_2 to 2NH_3 —a six-electron process—the reduction of acetylene by nitrogenase is only a two-electron process, *ethylene* ($\text{H}_2\text{C}=\text{CH}_2$) being the final product. Hence, the reduction of acetylene to ethylene provides a straightforward method for measuring nitrogenase activity

(Figure 19.30). This technique, known as the *acetylene reduction assay*, is widely used in microbiology to detect and quantify nitrogen fixation. Nitrogen fixation can also be assayed directly using the stable (nonradioactive) isotope ¹⁵N₂ and measuring its reduction to ¹⁵NH₃; however, acetylene reduction is a more rapid and sensitive method for measuring N₂ fixation and can easily be used in laboratory studies of pure cultures or ecological studies of nitrogen-fixing bacteria directly in their habitat. To do this, a sample, which may be soil, water, or a culture, is incubated in a vessel with HC≡CH and the gas phase is later analyzed by gas chromatography for the production of H₂C=CH₂ (Figure 19.30). The unique enzymatic

activity of nitrogenase—reduction of a triple bond—provides high confidence that acetylene reduction to ethylene measured in a natural sample is due to the activity of nitrogen-fixing bacteria.

Microsensors

Microsensors in the form of glass needles containing a sensing mechanism at the tip have been used to study the activity of microorganisms in nature. Microsensors have been constructed that measure many chemical species including pH, O₂, NO₂[−], NO₃[−], nitrous oxide (N₂O), CO₂, H₂, and H₂S. As the name *microsensor* implies, these devices are very small, their tips ranging in diameter from 2 to 100 μm (Figure 19.31). The sensors are carefully inserted into the habitat in small increments to follow microbial activities over very short distances.

Microsensors have many applications. For example, O₂ concentrations in microbial mats (► Figure 20.8c), aquatic sediments, or soil particles (► Figure 20.3) can be accurately measured over extremely fine intervals using microsensors. A micromanipulator is used to insert the sensors gradually through the sample such that measurements can be taken every 50–100 μm (Figure 19.32). Using a bank of microsensors, each sensitive to a different chemical, simultaneous measurements of several transformations in a habitat can be made.

Microbial processes in the sea are extensively studied because they have a profound impact on nutrient cycles and the overall health of the planet. As it is difficult to reproduce in the laboratory the conditions found at great depths, it is useful to use microsensors on robotic devices to analyze microbial activities on the seafloor. Figure 19.33 shows deployment of an instrument “lander” equipped with a suite of microsensors to detect various chemicals in the sediment. These data can then be analyzed and compared with that in overlying ocean water to explore the exchange of nutrients and other chemicals between water and sediment.

One of the biologically most important chemical species in the oceans is nitrate (NO₃[−]), but electrochemical sensors cannot measure NO₃[−] in seawater, as the high concentrations of salts interfere. To circumvent this problem, a “living” microsensor was designed

Figure 19.30 The acetylene reduction assay of nitrogenase activity in nitrogen-fixing bacteria. The results show no ethylene (C₂H₄) at time 0 but increasing production of C₂H₄ as the assay proceeds. As C₂H₄ is produced, a corresponding amount of C₂H₂ is consumed. Because the reduction of N₂ to 2 NH₃ requires 6 e[−] and the reduction of C₂H₂ to C₂H₄ only 2 e[−], each three C₂H₄ produced is equivalent to the reduction of one N₂.

Figure 19.31 Microsensors. (a) Schematic drawing of an oxygen (O₂) microsensor. Oxygen diffuses through the silicone membrane in the microsensor tip and reacts with electrons on the gold surface of the cathode, forming hydroxide ions (OH⁻); the latter generates a current proportional to the O₂ concentration in the sample. Note the scale of the electrode. (b) Biological microsensor for the detection of nitrate (NO₃⁻). Bacteria immobilized at the sensor tip denitrify NO₃⁻ or NO₂⁻ to N₂O, which is detected by electrochemical reduction to N₂ at the cathode. Based on drawings by Niels Peter Revsbech.

that contains bacteria within its tip that reduce NO₃⁻ (or NO₂⁻) to N₂O. The N₂O produced by the bacteria is then detected following its abiotic reduction to N₂ at the cathode of the microsensor (Figure 19.31b); this provides an electrical impulse signaling the presence of NO₃⁻. In the oxic layer of marine sediments, NO₃⁻ is produced from the oxidation of NH₄⁺ (nitrification, ◀ Section 14.9), so there is often a peak of NO₃⁻ in the sediment surface layer (Figure 19.32). In the deeper, anoxic layers of the sediment, NO₃⁻ is consumed by denitrification and dissimilative nitrate reduction to ammonia (DNRA) (◀ Section 14.11), and NO₃⁻ therefore disappears a few millimeters below the oxic–anoxic interface (Figure 19.32).

Figure 19.32 Depth profiles of O₂ and NO₃⁻. Data obtained using the lander shown in Figure 19.33 equipped with microelectrode sensors for remote chemical characterization of deep-sea sediments. Note the zones of nitrification and denitrification and the fine scale resolution. DNRA, dissimilative nitrate (NO₃⁻) reduction to ammonia (NH₄⁺). Based on data and drawings by Niels Peter Revsbech.

Sensor Nanoparticles for Spatially Resolved Chemical Imaging

An entirely different sensor approach to measuring biologically significant processes in the environment uses nanotechnology. Traditional microsensors only generate a single point measurement, and because of this, multiple measurements must be made, for example,

Figure 19.33 Deployment of a deep-sea lander. The lander is equipped with a bank of microsensors (arrow) to measure distribution of chemicals in marine sediments.

when measuring depth-related changes in O_2 concentration in a marine sediment (Figure 19.32). Hence, this approach is essentially unusable for examining chemical gradients in more than one dimension, such as on an uneven biological surface. To explore such microbial habitats, *sensor nanoparticles* have been developed that can be sprayed in a thin layer over the uneven surface. These tiny particles (from a few to several hundred nanometers in diameter) made from silica or synthetic polymers incorporate fluorescent or phosphorescent compounds that have a concentration-dependent luminescent response to specific chemicals. Biological nanosensors have been developed for assaying temperature, pH, O_2 , and a few ions of biological importance, such as Ca^{2+} and K^+ .

A study to measure changing O_2 distribution over a coral surface demonstrates the power of sensor nanotechnology (Figure 19.34). As we will learn in Chapter 23, stony corals are marine animals whose cells contain the symbiotic dinoflagellate *Symbiodinium*, an alga that nourishes the coral cells by carrying out photosynthesis. However, *Symbiodinium* is extremely sensitive to changes in temperature and irradiation associated with climate change. When growth conditions become unfavorable, the symbiont can be expelled and the coral bleached, and this has resulted in the extensive loss of living coral reefs worldwide in recent years (► Figure 23.41). To document these changes experimentally, ecological studies of oxygen-producing coral tissues were undertaken to measure the response of the symbiotic alga to changes in light intensity. To do this, a coral surface was covered with a thin layer of nanoparticles containing a fluorescent indicator for oxygen. Following calibration using an inert fluorescent reference dye also incorporated in the particles, the spatial

distribution of O_2 concentration was determined by taking fluorescent images of the coral under different levels of illumination, where oxygen levels can be seen to change quickly (Figure 19.34). When combined with nanosensors that respond to temperature differences, similar experiments should also be possible to measure coral responses to increasing ocean temperatures, an environmental variable thought to be a major trigger of the massive coral die-offs seen in recent years. By establishing links between coral structural organization, light, temperature, and chemical microenvironments, these analyses should yield important insights into factors that control the coral symbiosis and allow for more accurate predictions of how this important marine symbiosis will respond to climate change.

Other applications of nanosensor technology have been deployed or are on the horizon. For example, nanoparticles sensitive to both O_2 and pH have been used to examine the delivery of oxygen to the root systems of the seagrass *Zostera marina*. The observation of reduced pH and elevated oxygen close to the seagrass roots was attributed to oxygen delivered by the plant to support the growth of sulfur-oxidizing chemolithotrophs (◀ Sections 14.7 and 15.12), bacteria that oxidize the toxic hydrogen sulfide (H_2S); the resulting H_2SO_4 acidifies the roots, lowering the pH.

Although ecological applications of nanotechnology are still in their infancy, it is likely that in coming years more chemically diverse sensor particles will be developed and their use will become more widespread because of their unique ability to track gradients of microbial activity along uneven surfaces.

Figure 19.34 Oxygen nanosensor analysis of coral photosynthetic activity. (a) Calibration of nanosensor response to different dissolved oxygen concentrations using a fragment of a coral skeleton painted with the nanosensor octaethylporphyrin ketone platinum (II). (b) Living coral response to transition from darkness (top panel) to light (bottom panel). Note how the oxygen-depleted region due to coral respiration in the dark panel (arrow) quickly becomes oxygenated in the light. (c) Upper panel, photomicrograph of a coral polyp showing the polyp mouth (arrow). The red color is not from nanoparticles but is due to autofluorescence of chlorophyll in *Symbiodinium* cells present in the polyp and surrounding coral tissue. Lower panel, high-resolution profile from nanosensor data of an oxygen gradient across a polyp similar to that shown in the upper panel following transition to darkness. The scale on the abscissa indicates the small size of a polyp. The figure data and components in parts a and b were generated by Dr. Klaus Koren (Department of Bioscience, University of Aarhus) and Dr. Michael Kühl (Department of Biology, University of Copenhagen) with technical assistance from Sofie Lindegaard Jakobsen (Department of Biology, University of Copenhagen).

19.10 Stable Isotopes and Stable Isotope Probing

Many of the chemical elements have more than one isotope, which differ in their number of neutrons. Certain isotopes are unstable and break down as a result of radioactive decay. Others, called *stable isotopes*, are not radioactive, but are metabolized differently by microorganisms and can be used to study microbial transformations in nature. There are two methods in which stable isotopes can yield information on microbial activities, *isotopic fractionation* and *stable isotope probing*.

Figure 19.35 Mechanism of isotopic fractionation with C as an example. Enzymes that fix CO₂ preferentially fix the lighter isotope (¹²C). This results in fixed carbon being enriched in ¹²C and depleted in ¹³C relative to substrate CO₂. The size of the arrows indicates the relative abundance of each isotope of carbon.

Isotopic Fractionation

The two elements most useful for stable isotope studies in microbial ecology are carbon (C) and sulfur (S), although the heavy isotope of nitrogen, ¹⁵N, is also widely used. Carbon (C) exists in nature primarily as ¹²C, but about 5% exists as ¹³C. Likewise, S with its four stable isotopes exists primarily as ³²S. Some S is found as ³⁴S, and very small amounts as ³³S and ³⁶S. The relative abundance of these isotopes changes when certain C or S compounds are metabolized by microorganisms because the enzymes that act on these compounds typically favor the *lighter* isotope of C or S. That is, relative to the lighter isotope, the heavier isotope is discriminated against when both are metabolized by an enzyme (Figure 19.35).

For example, when CO₂ is fixed into cell material by an autotrophic organism, the cellular C becomes *enriched* in ¹²C and *depleted* in ¹³C, relative to an inorganic carbon standard of known isotopic composition. Likewise, the S atom in H₂S produced from the bacterial reduction of SO₄²⁻ is isotopically lighter than H₂S that has formed geochemically. These discriminations are called **isotopic fractionations** (Figure 19.35) and are typically the result of biological activities. Thus this technique can be used as a measure of whether a particular transformation has been catalyzed by microorganisms.

The isotopic fractionation of C in a sample is calculated as the extent of ¹³C depletion relative to a standard having an isotopic composition of geological origin. The standard for C isotope analysis is rocks from a Cretaceous (65- to 150-million-year-old) limestone formation (the Pee Dee belemnite). Because the magnitude of fractionation is usually very small, depletion is calculated as “per mil” (‰, or parts per thousand) and reported as the δ¹³C (pronounced “delta C 13”) of a sample using the following formula:

$$\delta^{13}\text{C} = \frac{(^{13}\text{C}/^{12}\text{C} \text{ sample}) - (^{13}\text{C}/^{12}\text{C} \text{ standard})}{(^{13}\text{C}/^{12}\text{C} \text{ standard})} \times 1000\text{‰}$$

The same formula is used to calculate the fractionation of S isotopes, in this case using iron sulfide (FeS) mineral from the Canyon Diablo meteorite as the standard:

$$\delta^{34}\text{S} = \frac{(^{34}\text{S}/^{32}\text{S} \text{ sample}) - (^{34}\text{S}/^{32}\text{S} \text{ standard})}{(^{34}\text{S}/^{32}\text{S} \text{ standard})} \times 1000\text{‰}$$

Use of Isotopic Fractionation in Microbial Ecology

The isotopic composition of a material can reveal its biological or geological past. For example, plant material and petroleum (which is derived from plant material) have similar isotopic compositions (Figure 19.36). Carbon from both plants and petroleum is isotopically lighter than the CO₂ from which it was formed because the biochemical pathway used to fix CO₂ discriminated against ¹³CO₂ (Figures 19.35 and 19.36). Moreover, methane (CH₄) produced by methanogenic *Archaea* (Section 17.2) is isotopically extremely light, indicating that methanogens discriminate strongly against ¹³CO₂ when they reduce CO₂ to CH₄ (Section 14.15). By contrast, carbon in isotopically heavier marine carbonates is clearly of geological origin (Figure 19.36).

Because of the differences in the proportion of ¹²C and ¹³C in carbon of biological versus geological origin, the ¹³C/¹²C ratio of rocks of different ages has been used as evidence for or against past biological activity in Earth’s ancient environments. Organic C in rocks as old as 3.5 billion years shows evidence of isotopic fractionation (Figure 19.36), supporting the idea that autotrophic life existed at this time. Indeed, we now believe that the first life on Earth appeared somewhat before this, about 3.8–3.9 billion years ago (Sections 1.5 and 13.1).

The activity of sulfate-reducing bacteria is easy to recognize from their fractionation of stable S isotopes in sulfides (Figure 19.37). As compared with an H₂S standard, sedimentary H₂S is highly enriched in ³²S (depleted in ³⁴S, Figure 19.37). Fractionation during sulfate reduction allows one to identify biologically produced S and has been widely used to trace the activities of sulfur-cycling *Bacteria* and *Archaea* through geological time. Sulfur isotopic analyses have also been used as evidence for the lack of life on the Moon. For example, the data in Figure 19.37 show that the isotopic composition of

Figure 19.36 Isotopic geochemistry of ¹³C and ¹²C. Note that C fixed by autotrophic organisms is enriched in ¹²C and depleted in ¹³C. Methane formed from the reduction of CO₂ with H₂ by methanogenic *Archaea* shows extreme isotopic fractionation.

Figure 19.37 Isotopic geochemistry of ^{34}S and ^{32}S . Note that H_2S and S^0 of biogenic origin are enriched in ^{32}S and depleted in ^{34}S .

sulfides in lunar rocks closely approximates that of the H_2S standard, which represents primordial Earth, and differs from that of microbially produced H_2S .

Stable Isotope Probing

Beyond stable isotope fractionation, an alternative stable isotope method called **stable isotope probing (SIP)** can be used to identify an organism or organisms carrying out the transformation of a nutrient labeled with a specific stable heavy isotope, such as ^{13}C or ^{15}N or even ^{18}O (the lighter, more common isotopes of these elements are ^{12}C , ^{14}N , and ^{16}O , respectively). The idea behind SIP is that the label will be selectively incorporated only into the cellular material of organisms actively metabolizing the nutrient. Then, following the isolation and sequencing of isotopically labeled DNA, the organisms carrying out the transformation can be identified.

Stable isotope probing can be used to ask general to more specific questions. For example, if ^{13}C -labeled benzoate were added to a sediment sample and the sample incubated for an appropriate period, the ^{13}C label would end up in the DNA of the organism (or

organisms) that metabolized the benzoate (Figure 19.38). Thus, although all DNA from the sample would be isolated, the ^{13}C -DNA is heavier, albeit only slightly heavier, than ^{12}C -DNA, and this difference is sufficient to separate the DNAs by a special type of centrifugation technique (Figure 19.38). Once the ^{13}C -DNA is isolated, it can be analyzed for phylogenetic genes or metabolic genes to yield genomic information about the benzoate degrader(s) in the sample. If instead of an organic compound, the experimental study focused on nitrogen fixation (conversion of N_2 to cell nitrogen, Section 3.12), $^{15}\text{N}_2$ could be supplied to a sample. When nitrogen fixers in the sample incorporate this, they will produce slightly heavier DNA than organisms that cannot fix nitrogen, and the heavier DNA can be isolated and analyzed for genes of interest.

SIP can also be used in combination with metagenomics to pinpoint organisms carrying out a specific metabolism (from SIP results) in the context of all the other species and metabolisms present in the sample (as revealed by metagenomic results). Besides a phylogenetic “hit” from the SIP results, additional genomic analyses of the labeled DNA could reveal functional genes required for the specific metabolism. Moreover, the phylogenetic and functional results from the SIP experiment could be further confirmed from the metagenomic profile. Clearly many opportunities exist for blending SIP and metagenomics to study important ecological problems.

Check Your Understanding

- What is the simplest explanation for why lunar sulfides are isotopically similar to those of the primordial Earth?
- What is the expected isotopic composition of carbon in methanotrophs (bacteria that consume CH_4)?
- How might exchange of metabolites among members of a microbial community complicate interpretation of a stable isotope probe experiment?

19.11 Linking Functions to Specific Organisms

The isotopic methods described thus far used samples containing large numbers of cells to infer that specific metabolisms were occurring within a community or in particular species within the

Figure 19.38 Stable isotope probing. The microbial community in an environmental sample is fed a ^{13}C substrate. Organisms that can metabolize the substrate produce ^{13}C -DNA as they grow and divide; ^{13}C -DNA can be separated from lighter ^{12}C -DNA by density gradient centrifugation (photo). The isolated DNA is then subjected to specific gene analysis or entire genomic analysis.

community. These methods give an overview of community activities but do not reveal the contribution of individual cells. To do this, new methods have been developed that can measure the activity and the elemental and isotopic composition of single cells. These are powerful methods for connecting cells of a specific microbial population with a specific activity or ecological niche, but in most cases, the phylogeny of the organisms of interest must be known in order to develop the necessary FISH probes (Section 19.5). Single-cell methods have been of particular importance to the study of metabolite exchange among microorganisms, such as exchanges involved in syntrophic relationships (◀ Section 14.22), where close physical association is essential for efficient exchange.

Single-Cell Metabolisms Imaged by Secondary Ion Mass Spectrometry (SIMS)

Secondary ion mass spectrometry (SIMS) is based on the detection of ions released from a sample placed under a focused high-energy primary ion beam, for example, of cesium (Cs^+); from the data generated, the elemental and isotopic composition of released materials can be obtained. When the primary ion beam impacts the sample, most chemical bonds are broken and atoms or polyatomic fragments are ejected from a very thin layer (1–2 nm) of the surface as either neutral or charged particles (secondary ions), a process called *sputtering*. These secondary ions are directed to a mass spectrometer, an instrument that can determine their mass-to-charge ratio.

NanoSIMS instruments are SIMS devices designed to yield information on single cells. The instrument is equipped with Cs^+ and O_2 primary beam sources with a resolution of 50 nm for the Cs^+ ion beam and 200 nm for the O_2 beam. The O_2 beam generates positive secondary ions and is used to analyze metals (e.g., Fe, Na, Mg) while the Cs^+ beam generates negative secondary ions for the analysis of major cellular elements (C, N, P, S, O, H) and halogens. The NanoSIMS instrument also records where on the specimen the ion beam

is directed such that a two-dimensional image of the distribution of specific ions on the sample surface is obtained. In addition, by focusing the ion beam on the same spot during repeated cycles of sputtering, material can be slowly burned away to expose deeper regions of the sample. This high-resolution SIMS analysis is where the term *NanoSIMS* got its name. NanoSIMS instruments have multiple detectors that provide for the simultaneous analysis of ions of different mass-to-charge ratios originating from the same sample location (Figure 19.39a).

When NanoSIMS is combined with FISH (Section 19.5) in a technology called *FISH-SIMS*, the incorporation of different elements, natural isotopes, or isotope-labeled substrates can be tracked into individual cells of specific cell populations. A variation on the FISH-SIMS method that simplifies the identification of cells scanned by NanoSIMS uses probe-conferred deposition of a halide (Br, F, I), either through direct incorporation of the halide into an oligonucleotide probe or by using a halide-containing tyramide substrate (see CARD-FISH, Section 19.5). Halogens possess a high ionization yield compared with other elements and are thus easy to detect and are typically of low natural abundance. Using this technology, one of the NanoSIMS detectors is dedicated to identifying cells to which the probe has hybridized (Figure 19.39d) by halogen ionization while the remaining detectors are used for assessing elemental composition (Figure 19.39c).

Because of its excellent spatial resolution, NanoSIMS technology is being increasingly used to examine metabolite transfer among single cells of interacting microorganisms. For example, labeling with $^{15}\text{N}_2$ followed by NanoSIMS was used to demonstrate the transfer of N_2 fixed by filamentous cyanobacteria to attached heterotrophic bacteria (Figure 19.39c). Labeling with $^{15}\text{NH}_4$ and ^{13}C -labeled CO_2 or organic substrates is also being used to explore the assimilation of key nutrients and the transfer of metabolites among microbial species in both aquatic and soil microbial communities.

Figure 19.39 NanoSIMS technology. (a) Schematic of NanoSIMS operation showing the beams of primary (red) and secondary (blue) ions and five different detectors, each of which identifies ions of a different mass-to-charge ratio. (b–d) Demonstration of interspecies nutrient transfer from a filamentous

cyanobacterium (*Anabaena*) to a *Rhizobium* species attached to the cyanobacterial heterocyst. The coculture was incubated with $^{15}\text{N}_2$, and the transfer of ^{15}N -labeled compounds from *Anabaena* to *Rhizobium* was imaged using a combination of enhanced elemental labeling–FISH (EL-FISH, a technique that

allows for simultaneous fluorescence and halogen labeling) and NanoSIMS. (b) Total ^{12}C abundance shown by gray tones. (c) ^{15}N enrichment. (d) ^{19}F abundance conferred by a probe that hybridizes only to the attached rhizobial cells (EL-FISH).

Figure 19.40 Raman microspectroscopic analysis of single cells. A cell of *Acanthamoeba* containing FISH-stained chlamydial symbionts (inset photo, arrows point to blue chlamydial cells) and Raman spectroscopy of isolated chlamydial cells. After incubation for 72 and 120 h in medium containing ^{13}C phenylalanine, symbionts were released by lysis of the amoeba and their Raman spectra recorded. Peaks diagnostic for labeled phenylalanine are shown in red. Since the Raman wave number of ^{13}C phenylalanine at 967 cm^{-1} is well resolved from other spectral features, the ratio of 1003 cm^{-1} (unlabeled phenylalanine, at *) to 967 cm^{-1} (labeled phenylalanine) peak areas corresponds to the relative amount of labeled phenylalanine incorporated by single cells (note how this increases with time). Other red peaks correspond to spectral peaks specific for different chemical bonds in ^{13}C phenylalanine. Also shown are selected peaks and their wave numbers for other cellular components of the symbiont.

Raman Microspectroscopy

Raman microspectroscopy can be used to characterize the molecular and isotopic composition of single cells by nondestructive illumination with monochromatic light generated by a laser. Raman is a form of spectroscopy that measures light scattering and can yield both qualitative and quantitative results. Compositional analysis is based on photon scattering after interaction with different cellular components. Although most of the scattered photons have the same energy as the incident photons, a small fraction of scattered photons are shifted in wavelength (relative to the incident wavelength) to either a longer wavelength (a phenomenon known as *Stokes Raman scattering*) or shorter wavelength (*anti-Stokes scattering*).

Raman spectrometers separate the more abundant Stokes scattered photons for analysis and, when combined with confocal microscopy (◀ Section 1.9), can generate a compositional spectrum of a single microbial cell (Figure 19.40). Although the spectrum is complex, several compounds and molecules have characteristic peaks that can identify specific cell types, physiological states, or metabolic activities following incorporation of compounds labeled with stable isotopes.

Major advantages of Raman microspectroscopy include the following: It is nondestructive and can be used on living cells; water does not cause interference; it can be combined with FISH; and cells

of interest can be further manipulated, for example, through capture by laser tweezers (Section 19.3). In the example of Raman shown in Figure 19.40, the incorporation of phenylalanine (an amino acid) by an obligate chlamydial symbiont of an amoeba has been tracked following addition of phenylalanine labeled with ^{15}N and ^{13}C to the amoeba growth medium. A less specific but still useful application of Raman is based on the incorporation of heavy protons from deuterated water ($^2\text{H}_2\text{O}$). Since water is a reactant in many biochemical reactions, metabolically active microorganisms that incorporate the heavy hydrogen atom can be identified by Raman microspectroscopy for further processing, including characterization by single-cell genomics (◀ Section 10.11).

Radioisotopes in Combination with FISH: Microautoradiography-FISH

Radioisotopes are used as measures of microbial activity in a microscopic technique called **microautoradiography (MAR)**. In this method, cells from a microbial community are exposed to a substrate containing a radioisotope, such as an organic compound or CO_2 . Heterotrophs take up the radioactive organic compounds and

(a)

(b)

(c)

Figure 19.41 MAR-FISH. Fluorescence in situ hybridization (FISH) combined with microautoradiography (MAR). (a) An uncultured filamentous cell belonging to the *Gammaproteobacteria* (as revealed by FISH) is shown to be an autotroph (as revealed by MAR-measured uptake of $^{14}\text{C}\text{CO}_2$). (b) Uptake of ^{14}C -glucose by a mixed culture of *Escherichia coli* (yellow cells) and *Herpetosiphon aurantiacus* (filamentous green cells). (c) MAR of the same field of cells shown in part b. The radioactivity of incorporated glucose exposes the film and shows that glucose was assimilated mainly by cells of *E. coli*.

autotrophs take up the radioactive CO_2 . Following incubation in the substrate, cells are affixed to a slide and the slide is dipped in photographic emulsion. While the slide is left in darkness for a period, radioactive decay from the incorporated substrate induces formation of silver grains in the emulsion; these appear as black dots above and around the cells. **Figure 19.41a** shows a MAR experiment in which an autotrophic cell has taken up $^{14}\text{CO}_2$.

Microautoradiography can be done simultaneously with FISH (Section 19.5) in **MAR-FISH**, a powerful technique that combines identification with activity measurements. MAR-FISH allows a microbial ecologist to determine (by MAR) which organisms in a natural sample are metabolizing a particular radiolabeled substance while at the same time identifying these organisms (by FISH) (Figure 19.41b, c). MAR-FISH thus goes a step beyond phylogenetic identification by revealing physiological information about the organisms, as is also true of NanoSIMS. Such data are useful not only for understanding the activity of the microbial ecosystem but also for guiding enrichment cultures. For example, knowledge of the phylogeny and morphology of an organism metabolizing a particular substrate in a natural sample can be used to design an enrichment protocol to isolate the organism. In addition, MAR-FISH results can be quantified by counting the silver grains as a measure of the amount of substrate consumed by single cells, allowing the activity distribution in a community to be described. The technique is limited only by the availability of suitable radioactive isotopes. For example, although C-labeled substrates work well, it is not feasible to track N incorporation using MAR-FISH because the radioactive isotope ^{13}N has a very short half-life. However, it is feasible to track N incorporation using the nonradioactive stable isotope ^{15}N with NanoSIMS, as we saw earlier (Figure 19.39).

Check Your Understanding

- Why is Raman microspectroscopy suited for the selective isolation of microorganisms and NanoSIMS is not?
- How does MAR-FISH link microbial diversity and activity?

19.12 Linking Genes and Cellular Properties to Individual Cells

We have seen in the previous section how the combination of FISH with MAR or FISH with NanoSIMS allows for analyses of both microbial diversity and activity. Coupled with advanced DNA sequencing methods that can determine a genome sequence from the DNA contained in a single cell (◀ Section 10.11), these techniques are at the cutting edge of microbial ecology today. Improvements in single-cell DNA sequencing technology, combined with high-throughput analysis and isolation of single cells by flow cytometry, now allow for gene identification and selected physiological analyses (e.g., size and intrinsic fluorescence) to be performed on selected populations and single cells in the environment.

Flow Cytometry and Multiparametric Analyses

Because of the large population sizes of natural microbial communities, methods that rely on microscopy can examine only a very small part of a whole community. It is difficult to assess cell numbers by

counting cells microscopically, and this problem is compounded if populations are present in low numbers. However, flow cytometry (Section 19.3) offers an alternative to more labor-intensive microscopic methods.

Flow cytometers can examine specific cell parameters such as size, shape, or fluorescent properties as the cells pass through a detector at rates of many thousands of cells per second (**Figure 19.42**). Fluorescence may be intrinsic (for example, chlorophyll fluorescence of phototrophic microorganisms); or it may be conferred by DNA staining, by differential staining of live versus dead cells (vital stains), or by fluorescent DNA probes (FISH or BONCAT-FISH), all methods discussed earlier in this chapter.

A major advantage of flow cytometry is the ability to carry out *multiparametric analyses*, that is, the capacity to combine multiple parameters in the analysis of a microbiological sample or to sort

Figure 19.42 Flow cytometric cell sorting. As the fluid stream exits the nozzle, it is broken into droplets containing no more than a single cell. Droplets containing desired cell types (detected by fluorescence or light scatter) are charged and collected by redirection into collection tubes or microtiter plates by positively or negatively charged deflection plates. DNA recovered from a specific population of cells or amplified from a single cell (◀ Figure 10.30) is characterized by PCR amplification and sequencing of specific genes or by full genome sequence analysis.

cells in order to find a specific population. A good example of this was the discovery in the late 1980s of a novel and abundant community of marine cyanobacteria, all species of the genus *Prochlorococcus*. *Prochlorococcus* cells are smaller and have different fluorescent properties than another common marine cyanobacterium, *Synechococcus*. Based on differences in size and fluorescence, flow cytometry resolved these two populations and *Prochlorococcus* was subsequently shown to be the predominant oxygenic phototroph in ocean waters between 40°S and 40°N latitude, reaching concentrations greater than 10^5 cells/ml. Metagenomics has also been used to identify the unique genomic features of different natural populations of *Prochlorococcus* (Figure 19.24). These findings have led to the conclusion that *Prochlorococcus* is the most abundant phototrophic organism on Earth. We discuss the biology of *Prochlorococcus* in more detail in Section 20.11.

Single-Cell Genomics

A major stumbling block in a PCR-based gene recovery method is the requirement that a specific gene that will react with the primers used in the amplification be identified prior to analysis. Newer methods of DNA amplification now provide an alternative method for associating specific genes with a specific organism without the problems and biases associated with PCR. These methods employ *single-cell genomics* (◀ Section 10.11), one of the more recent tools to enter the microbial ecologist's toolbox. As discussed in Chapter 10, when combined with methods for recovery of single cells and high-throughput DNA sequencing methods, single-cell genome sequencing provides a powerful tool for linking specific metabolic functions to individual cells that have never been grown in laboratory culture.

Multiple displacement amplification (MDA) (Figure 19.43) is key to single-cell genomics because it can amplify chromosomal DNA from a single cell isolated from a natural environment using a cell sorting technique, such as flow cytometry (Figure 19.42). MDA uses a specific bacteriophage DNA polymerase to initiate replication of cell DNA at random points in the chromosome, displacing the complementary strand as each polymerase molecule synthesizes new DNA. The phage polymerase has strong strand displacement activity, resulting in the synthesis of numerous high-molecular-weight DNA products at very high fidelity. The number of genome copies produced by MDA is usually sufficient to assemble the complete, or nearly complete, genome of the cell that yielded the DNA using next-generation sequencing platforms and powerful sequence analysis software. In this way, both phylogenetic and metabolic functions can be inferred from the genome sequence and PCR is not required. PCR can be a problem if there exists a bias in the genome against the primers used. MDA avoids this by annealing random rather than specific primers to the genomic DNA such that amplification of the entire genome is highly likely.

Not surprisingly, MDA requires stringent control over purity to eliminate contaminating DNA, but when combined with high-throughput DNA sequencing methods, MDA provides a powerful tool for linking specific metabolic functions to individual cells that have thus far eluded laboratory culture. Information about the metabolic capacities of these uncultured organisms can then be used to

Figure 19.43 Genetic analyses of sorted cells. DNA is recovered from a specific population of cells following FISH labeling and flow cytometric sorting (Figure 19.42). DNA is characterized by PCR amplification and sequencing of specific genes, or by amplification of the entire genome by multiple displacement amplification (MDA) followed by sequencing. For MDA, an amount of DNA sufficient for full genome sequence determination is produced using short DNAs of random sequence as primers (A) to initiate genome replication by a bacteriophage DNA polymerase. The bacteriophage polymerase copies DNA from multiple points in the genome and also displaces newly synthesized DNA (B, C), thereby freeing additional DNA for primer annealing and (D) initiation of polymerization.

develop strategies to recover them by either classical enrichment and isolation methods (Sections 19.1 and 19.2) or by any of the several single-cell isolation culturing techniques now available to tease out individual cells and get them growing in the laboratory (Section 19.3 and Figure 19.42).

A Preview of What's to Come

Now that we have some background on how we can track and identify microbes in nature and assess their activities, we will use these tools as we move on to the next chapter to consider where microbes actually live in nature. In Chapter 20 we will link microbial diversity with major habitats to answer the questions “Who is where?” and

“Why are they there?” In Chapter 21 we will connect diversity with metabolism to explore the major nutrient cycles in nature that are driven by microbial activities. In Chapter 22 we will consider microbes and their habitats once again but in the context of microbes that reside in our buildings, subways, and other major structures constructed by humans. Chapters 23 and 24 also link microbes to habitats but in the context of the many symbiotic associations that microbes have developed with plants and animals, including ourselves. Background on where microbes live in nature and why is the natural introduction to the final two units in this text

where we focus on microbe–human relationships, both the highly beneficial and the life-threatening.

Check Your Understanding

- Compared with microscopy, what are the advantages and disadvantages of flow cytometry for characterizing a microbial community?
- What key method is required to do genomics on a single cell?

Go to **Mastering Microbiology** for videos, animations, practice tests, and more.

CHAPTER REVIEW

I • Culture-Dependent Analyses of Microbial Communities

- 19.1** The enrichment culture technique is a means of obtaining microorganisms from natural samples. Successful enrichment and isolation prove that an organism of a specific metabolic type was present in the sample, but do not indicate its ecological importance or abundance. Enrichments following dilution of the sample often yield different organisms than enrichments with undiluted samples.

Q What exactly constitutes an enrichment culture? What should an effective enrichment culture duplicate?

- 19.2** Once a successful enrichment culture has been established, pure cultures can often be obtained by conventional microbiological procedures, including streak plates, agar dilution, and liquid dilution methods.

Q Describe how an appropriate inoculum can be used to successfully start an enrichment culture.

- 19.3** Several methods are available to isolate and culture single cells. Laser tweezers allow one to isolate a cell from a microscope field and move it away from contaminants. Flow cytometric sorting combined with high-throughput culturing technology allow for isolated cells to be cultured in a large variety of culture media simultaneously to identify the resources and conditions best suited to the growth of the isolated cell.

Q It is thought that every microbe has a fundamental niche and a realized niche. How does a fundamental niche differ from a realized niche?

II • Culture-Independent Microscopic Analyses of Microbial Communities

- 19.4** DAPI, acridine orange, and SYBR Green are general stains for quantifying microorganisms in natural samples. Some stains can differentiate live versus dead cells. The GFP makes cells autofluorescent and is a means for tracking cells introduced

into the environment and reporting gene expression. In natural samples, morphologically identical cells may actually be genetically distinct.

Q What are dyes that stain DNA used for? Is background staining a problem when using such dyes?

- 19.5** FISH methods have combined the power of nucleic acid probes with fluorescent dyes and are thus highly specific in their staining properties. FISH methods include phylogenetic stains, CARD-FISH, and BONCAT-FISH. Using fluorescence microscopy, CARD-FISH can identify transcriptionally active cells while BONCAT-FISH can identify translationally active cells.

Q Compare and contrast CARD-FISH and BONCAT-FISH. Why are these methods more suitable than FISH for characterizing very slowly growing microorganisms in the environment?

III • Culture-Independent Molecular Analyses of Microbial Communities

- 19.6** PCR can be used to amplify specific target genes such as rRNA genes or key metabolic genes for subsequent analysis of community structure and potential functions. DGGE and T-RFLP can identify the different variants of these genes among the species in a community. Application of ARISA is limited to amplification of the internal transcribed spacer region separating the 16S and 23S rRNA genes.

Q Which method, ARISA or T-RFLP, would provide more detail about microbial community complexity? Why?

- 19.7** In current application, microarrays used for environmental studies primarily consist of thousands of DNA probes that hybridize to specific genes encoding key biochemical processes.

Q Why might a microarray be superior to using high-throughput sequencing to quantify both abundant and rare gene sequences in a complex microbial community? What are the limitations of functional microarrays, such as the GeoChip, for analysis of microbial communities?

- 19.8** Environmental multi-omics uses different combinations of metagenomics, metatranscriptomics, metaproteomics, and metabolomics to derive deeper understanding of how microbial diversity relates to the complex metabolic food webs sustaining natural microbial communities and associated biogeochemical processes.

Q Give an example of how multi-omics has contributed to a better understanding of microbial food web structure. Why is the use of environmental genomic information alone often insufficient to discover new biochemical properties?

IV • Measuring Microbial Activities in Nature

- 19.9** The activity of microorganisms in natural samples can be assessed very sensitively using radioisotopes or microsensors, or both. The measurements obtained give the net activity of the microbial community.

Q What are the major advantages of radioisotopic methods in the study of microbial ecology? What type of controls (discuss at least two) would you include in a radioisotopic experiment to show $^{14}\text{CO}_2$ incorporation by cyanobacteria or to show ^{14}C -glucose incorporation by anaerobic bacteria?

- 19.10** Natural isotopic composition, the result of isotopic fractionation by enzymes that discriminate against the heavier form of an element, can reveal the biological origin and/or biochemical mechanisms involved in the formation of various substances. Stable isotope probing (SIP) uses compounds labeled with isotopes not naturally abundant

to identify microorganisms metabolizing and assimilating the compound added to a community.

Q Will autotrophic organisms contain more or less ^{12}C in their organic compounds than was present in the CO_2 that fed them? Why would SIP using $^{15}\text{NO}_3^-$ not be useful for identifying bacteria carrying out nitrate respiration?

- 19.11** A variety of advanced technologies such as NanoSIMS, MAR-FISH, BONCAT-FISH, and Raman microspectroscopy make it possible to examine metabolic activity, gene content, and gene expression of single cells in natural microbial communities. NanoSIMS employs secondary ion mass spectrometry technology. MAR-FISH combines the uptake of radiolabeled substrates (MAR) along with phylogenetic identification (FISH). Raman microspectroscopy is a non-destructive method (retaining cell viability).

Q What can MAR-FISH tell you that FISH alone cannot? How might you combine SIP and NanoSIMS to identify novel methane-consuming cells in a natural community?

- 19.12** Flow cytometry combined with cell sorting can rapidly evaluate many thousands of single cells in a natural environment for basic cellular properties (size, shape) or gene content (using specific fluorescent probes). Single-cell genomics incorporates methods for use on individual cells from a natural microbial community, for example, by flow cytometric isolation of cells and multiple displacement amplification to obtain genome sequences of single cells.

Q How would you use cytometric cell sorting to evaluate genome sequence variation among a population of marine bacteria present in low abundance?

APPLICATION QUESTIONS

- Design an experiment for measuring the activity of sulfur-oxidizing bacteria in soil. If only certain species of the sulfur oxidizers present were metabolically active, how could you tell this? How would you prove that your activity measurement was due to biological activity?
- You wish to know whether *Archaea* exist in a lake water sample but are unsuccessful in culturing any. Using techniques described in this chapter, how could you determine whether *Archaea* exist in the sample, and if they do, what proportion of the cells in the lake sample are *Archaea*?
- Design an experiment to solve the following problem: Determine the rate of methanogenesis ($\text{CO}_2 + 4 \text{H}_2 \rightarrow \text{CH}_4 + 2 \text{H}_2\text{O}$) in anoxic lake sediments and whether or not it is H_2 -limited. Also, determine the morphology of the dominant methanogen (recall that these are *Archaea*, ◀ Section 17.2). Finally, calculate what percentage the dominant methanogen is of the total archaeal and total prokaryotic populations in the sediments. Remember to specify necessary controls.
- Design a SIP experiment that would allow you to determine which organisms in a lake water sample were capable of oxidizing the hydrocarbon hexane (C_6H_{14}). Assume that four different species could do this. How would you combine SIP with other molecular analyses to identify these four species?

CHAPTER GLOSSARY

Acridine orange a nonspecific fluorescent dye used to stain DNA in microbial cells in a natural sample

BONCAT-FISH a method to identify translationally active cells labeled by FISH by

incorporating a noncanonical amino acid into their proteins followed by coupling it to a fluorescent reporter molecule (BONCAT stands for bioorthogonal noncanonical amino acid tagging)

DAPI a nonspecific fluorescent dye that stains DNA in microbial cells; used to obtain total cell numbers in natural samples

Denaturing gradient gel electrophoresis (DGGE) an electrophoretic technique

capable of separating nucleic acid fragments of the same size that differ in base sequence

Enrichment bias a problem with enrichment cultures in which “weed” species tend to dominate in the enrichment, often to the exclusion of the most abundant or ecologically significant organisms in the inoculum

Enrichment culture a culture that employs highly selective laboratory methods for obtaining microorganisms from natural samples

Environmental genomics (metagenomics) the use of genomic methods (sequencing and analyzing genomes) to characterize natural microbial communities

Exometabolite a product of metabolism released from a cell that may be metabolized by other organisms

Flow cytometry a technique for counting and examining microscopic particles by suspending them in a stream of fluid and passing them by an electronic detection device

Fluorescence in situ hybridization (FISH) a method employing a fluorescent dye covalently bonded to a specific nucleic acid probe for identifying or tracking organisms in the environment

Fluorescent protein any of a large group of proteins that fluoresce different colors, including the green fluorescent protein, for tracking genetically modified organisms and determining conditions that induce the expression of specific genes

Fundamental niche the range of environments in which a species will be sustained when it is not resource-limited, such as may result from competition with other species

Green fluorescent protein (GFP) a protein that fluoresces green and is widely used in genetic analysis

High-throughput culturing methods

the use of microtiter plates whose wells contain various culture media that can be inoculated with single cells whose growth or target gene content is measured robotically

Isotopic fractionation the discrimination by enzymes against the heavier isotope of the various isotopes of C or S, leading to enrichment of the lighter isotopes

Laser tweezers a device for obtaining pure cultures by optically trapping a single cell with a laser beam and moving it away from surrounding cells into sterile growth medium

MAR-FISH a technique that combines identification of microorganisms by FISH with measurement of metabolic activities by microautoradiography (MAR)

Metabolomics the comprehensive analysis of cellular and extracellular metabolites of a cell, organism, or microbial community

Metaproteomics the measurement of whole-community protein expression using mass spectrometry to assign peptides to the amino acid sequences encoded by unique genes

Metatranscriptomics the measurement of whole-community gene expression using RNA sequencing

Microautoradiography (MAR) the measurement of the uptake of radioactive substrates by visually observing the cells in an exposed photographic emulsion

Microbial ecology the study of the interaction of microorganisms with each other and their environment

Microfluidic devices miniaturized systems for fluid handling that are increasingly used for high-throughput culturing of microorganisms

Microsensor a small glass sensor or electrode for measuring pH or specific

compounds such as O_2 , H_2S , or NO_3^- that can be immersed into a microbial habitat at microscale intervals

Most-probable-number (MPN) technique the serial dilution of a natural sample to determine the highest dilution yielding growth

Multi-omics the integration of data from multiple omics platforms to more fully characterize microbial community structure and function

Multiple displacement amplification (MDA) a method to generate multiple copies of chromosomal DNA from a single organism

Nucleic acid probe a strand of nucleic acid that can be labeled and used to hybridize to a complementary molecule from a mixture of other nucleic acids

Phylotype one or more organisms with the same or related sequences of a phylogenetic marker gene

Realized niche the range of natural environments supporting a species when that organism is confronted with factors such as resource limitation, predation, and competition from other species

Stable isotope probing (SIP) a method for characterizing an organism that incorporates a particular substrate by supplying the substrate in ^{13}C or ^{15}N form and then isolating heavy isotope-enriched DNA and analyzing the genes

Winogradsky column a glass column packed with mud and overlaid with water to mimic an aquatic environment, in which various bacteria develop over a period of months

Microbial Ecosystems 20

MICROBIOLOGYNOW

Living on Fumes

Antarctica is one of the harshest environments on Earth, experiencing extremely cold temperatures, high levels of ultraviolet radiation, and limited availability of carbon, nitrogen, and water. Even so, rocky desert Antarctic soils (photo) support microbial communities whose diversity rivals that of temperate soils. Cyanobacteria fix enough carbon dioxide (CO₂) to support heterotrophic communities in many soils of Antarctica. However, the virtual absence of cyanobacteria in some other Antarctic soils raises the question of what energy source (other than light) sustains these microbial communities.

Researchers combined metagenomics with biochemical measurements to probe this mystery. The first hint was the discovery of Calvin cycle genes for CO₂ fixation in *Actinobacteria* that composed about half of the total soil microbiota (the Calvin cycle is a major autotrophic pathway). Since these *Actinobacteria* are not phototrophic, CO₂ fixation—which requires ATP—had to be supported by energy sources other than sunlight. The answer again emerged from metagenomics by identifying genes in the *Actinobacteria* encoding aerobic respiration of molecular hydrogen (H₂) and

carbon monoxide (CO) and then showing that these genes were actively transcribed at below-freezing temperatures. Additionally, comparison of these gene sequences to those of cultured close relatives suggested these enzymes could scavenge H₂ and CO at the parts per billion concentrations typically found in Earth's lower atmosphere. This was subsequently confirmed by direct measurements of activity where it was shown that atmospheric concentrations of H₂ stimulated rates of CO₂ fixation sufficient to support about 10⁷ bacteria per gram of Antarctic soil.

Because low concentrations of H₂ and CO are constantly available, they are dependable energy sources for the slow-growing soil microbial communities in Antarctica. Whereas most ecosystems are sustained by solar or geologically derived energy, it appears that bacteria in some Antarctic surface soils are supported by atmospheric trace gases. In other words, these microbes are “living on fumes”!

Microorganisms do not live alone in nature but instead interact with other organisms and with their environment. In so doing, microorganisms carry out many essential activities that support all life on Earth. In this chapter we explore some of the major habitats of microorganisms; these include soil, freshwater, and the oceans. In addition to these, microbes have also established more specific, and often very intimate, associations with plants and animals. We examine a few examples of such microbial partnerships and symbioses in Chapters 23 and 24.

I • Microbial Ecology

Microbial ecology borrows many concepts from classical ecology but differs in the enormous diversity of microbial habitats and metabolisms it must consider—habitats and metabolisms that collectively drive the major nutrient cycles in nature and provide life support to all macroorganisms.

We begin with a broad overview of the science of microbial ecology, including ways that organisms interact with each other and their environments and the difference between species *diversity* and species *abundance*. These basic ecological concepts pervade this and the next three chapters.

20.1 General Ecological Concepts

The distribution of microorganisms in nature resembles that of macroorganisms in the sense that a given species resides in certain places but not others; that is, everything is not everywhere. Also, environments differ in their abilities to support diverse microbial populations, from the highly diverse microbial world of undisturbed fertile soil to the rather restricted world of some highly extreme environments.

Ecosystems and Habitats

An **ecosystem** is a dynamic complex of plant, animal, and microbial communities and their abiotic surroundings, all of which interact as a functional unit. An ecosystem contains many different **habitats**, parts of the ecosystem best suited to one or a few populations. Although microorganisms are present in any habitat containing

plants and animals, many microbial habitats are unsuitable for plants and animals. For example, microorganisms are ubiquitous on Earth's surface and even deep within it; they inhabit boiling hot springs and solid ice, acidic environments near pH 0, saturated brines, environments contaminated with radionuclides and heavy metals, and the interior of porous rocks that contain only traces of water. Therefore, some ecosystems are mostly or even exclusively microbial.

Collectively, microorganisms show great metabolic diversity and are the primary catalysts of nutrient cycles in nature (Chapter 21). The *types* of microbial activities possible in an ecosystem are a function of the species present, their population sizes, and the physiological state of the microorganisms in each habitat. By contrast, the *rates* of microbial activities in an ecosystem are controlled by the nutrients and growth conditions that prevail. Depending on several factors, microbial activities in an ecosystem can have minimal or profound impacts and can diminish or enhance the activities of both the microorganisms themselves and the macroorganisms that may coexist with them.

Species Diversity in Microbial Habitats

A group of microorganisms of the same species that reside in the same place at the same time constitutes a microbial **population** and may be descendants of a single cell. A microbial population differs from a microbial **community**. A community consists of populations living in association with other populations. The microbial species that reside in a certain habitat are those best able to grow with the nutrients and conditions that prevail there, and the number of different populations present is a measure of the community's complexity.

The diversity of microbial species in a community can be expressed in two ways: richness and abundance (Figure 20.1). **Species richness** is an expression of the total *number* of different species present. Identifying cells is, of course, basic to determining microbial species richness, but this need not require their isolation and culture. Species richness may also be expressed in molecular terms by the diversity of phylotypes (for example, the diversity of ribosomal RNA genes, ◀ Section 19.6) observed in a given community. **Species abundance**, by contrast, is the *proportion* of each species in the community (compare Figure 20.1*b* and *c*). Species richness and

(a)

(b)

Figure 20.1 Microbial species diversity: Richness versus abundance. (a) Collecting samples from Lake Taihu, China, following a bloom of the cyanobacterium *Microcystis*. (b) High species richness in St. John's River, Florida, shown by microscopy of planktonic microorganisms including cyanobacteria, diatoms, green algae, flagellates, and bacteria. (c) Shift of St. John's River community to low richness but high abundance following a bloom of the cyanobacterium *Microcystis*.

Hans Paerl, University of North Carolina at Chapel Hill

TABLE 20.1 Resources and conditions that govern microbial growth in nature
Resources Carbon (organic, CO ₂) Nitrogen (organic, inorganic) Other macronutrients (S, P, K, Mg) Micronutrients (Fe, Mn, Co, Cu, Zn, Mn, Ni) O ₂ and other electron acceptors (NO ₃ ⁻ , SO ₄ ²⁻ , Fe ³⁺) Inorganic electron donors (H ₂ , H ₂ S, Fe ²⁺ , NH ₄ ⁺ , NO ₂ ⁻)
Conditions Temperature: cold → warm → hot Water potential: dry → moist → wet pH: 0 → 7 → 14 O ₂ : oxic → microoxic → anoxic Light: bright light → dim light → dark Osmotic conditions: freshwater → marine → hypersaline

abundance can change quickly over a short time as shown by the change in abundance of cyanobacteria in a lake receiving nutrient-rich agricultural runoff (Figure 20.1a). One goal of microbial ecology is to understand what factors control species richness and abundance in microbial communities along with the community’s associated activities and the abiotic environment. Once all of these factors are known, microbial ecologists can model the ecosystem by perturbing it in some way and observing whether predicted changes match experimental results.

The microbial species richness and abundance of a community are functions of the conditions that prevail and the kinds and amounts of nutrients available in the habitat. Table 20.1 lists common nutrients and conditions relevant to microbial growth. In some microbial habitats, such as undisturbed organic-rich soils, high species richness is common (see Figure 20.14), with most species present at only moderate abundance. Nutrients in such a habitat are of many different types, and this helps select for high species richness. In other habitats, such as some extreme environments, species richness is often very low and abundance of one or a few species very high. This is because the physical and chemical conditions in the environment exclude all but a handful of species, and key nutrients are present at such high levels (Figure 20.1a) that the highly adapted species can grow to high cell densities. Bacteria that catalyze acid mine runoff from the oxidation of iron are an example of this. These organisms thrive in highly acidic, iron-rich but organic-poor waters, where the acidic conditions and the dearth of organic carbon limit species richness. However, the elevated levels of ferrous iron (Fe²⁺) present, which is oxidized to Fe³⁺ in energy-yielding reactions (◀ Section 14.8), fuel high species abundance. We examine the activities of acidophilic iron-oxidizing microorganisms in Sections 21.6, 21.1, and 22.2. Although the microbial diversity of extreme environments may at first seem mundane, extreme environments have been well-studied by microbial ecologists because the limited community complexity makes it easier to dissect the ecological interactions of the microbes that inhabit them.

Check Your Understanding

- What is the difference between species richness and species abundance?
- How does an ecosystem differ from a habitat?
- What are the characteristics of a microbial population?
- How does a microbial population differ from a microbial community?

20.2 Ecosystem Service: Biogeochemistry and Nutrient Cycles

In any ecosystem whose resources and growth conditions are suitable, microorganisms will grow to form populations. Metabolically similar microbial populations that exploit the same resources in a similar way are called **guilds**. A habitat that is shared by a guild and supplies the resources and conditions the cells require for growth is called a **niche**. Sets of guilds form microbial communities (Figure 20.2). Microbial communities interact with macroorganisms and abiotic factors in the ecosystem in a way that defines the workings of that ecosystem.

Energy Inputs to the Ecosystem

Energy enters ecosystems as sunlight, organic carbon, and reduced inorganic substances. Light is used by phototrophs to make ATP and synthesize new organic matter (Figure 20.2). In addition to carbon

Figure 20.2 Populations, guilds, and communities. Microbial communities consist of populations of cells of different species. A freshwater lake ecosystem would likely have the communities shown here. The reduction of NO₃⁻, Fe³⁺, SO₄²⁻, S⁰, and CO₂ are examples of anaerobic respirations. The region of greatest activity for each of the different respiratory processes would differ with depth in the sediment. As more energetically favorable electron acceptors are depleted by microbial activity near the surface, less favorable reactions occur deeper in the sediment. All guild metabolisms shown are described in Chapter 14.

(C), new organic matter contains nitrogen (N), sulfur (S), phosphorus (P), iron (Fe), and the other elements of life (◀ Section 3.1). This newly synthesized organic material along with organic matter that enters the ecosystem from the outside (called *allochthonous* organic matter) fuels the catabolic activities of chemoorganotrophic organisms. These activities oxidize the organic matter to CO_2 by respiration or ferment it to various reduced substances. If chemolithotrophs are present and metabolically active in the ecosystem, they can conserve energy from the oxidation of inorganic electron donors, such as H_2 , Fe^{2+} , S^0 , or NH_3 (Chapters 14 and 15), and contribute new organic matter through their autotrophic activities.

Biogeochemical Cycling

Microorganisms play an essential role in cycling elements, in particular C, N, S, and Fe, between their different chemical forms. The study of these transformations is part of **biogeochemistry**, an interdisciplinary science that includes biology, geology, and chemistry. Figure 20.2 shows how the activities of different guilds of microorganisms influence the chemistry of one environment, a lake ecosystem. The sequence of changing chemistry with increasing depth in the sediments corresponds to the layers of different microbial guilds. The location of each guild in the ecosystem is primarily determined by the availability of electron donors and acceptors, both of which tend to decrease with increasing depth in the sediments.

A *biogeochemical cycle* defines the transformations of an element that are catalyzed by either biological or chemical means (or both). Many different microorganisms participate in biogeochemical cycling reactions, and in many cases, microorganisms are the *only* biological agents capable of regenerating forms of the elements needed by other organisms, particularly plants. Thus, biogeochemical cycles are often also *nutrient cycles*, reactions that generate important nutrients for other organisms.

Most biogeochemical cycles proceed by oxidation–reduction reactions as the element moves through the ecosystem and are often tightly *coupled*, with transformations in one cycle affecting one or more other cycles. For example, hydrogen sulfide (H_2S) is oxidized by phototrophic and chemolithotrophic microbes to sulfur (S^0) and sulfate (SO_4^{2-}), the latter being a key nutrient for plants. Phototrophs and chemolithotrophs are also autotrophs, and thus affect the carbon cycle by producing new organic carbon from CO_2 . However, SO_4^{2-} can be reduced to H_2S by the sulfate-reducing bacteria, organisms that consume organic carbon, and this reduction closes the biogeochemical sulfur cycle while regenerating CO_2 . The cycling of nitrogen is also a microbial process and is key to the regeneration of forms of nitrogen usable by plants and other organisms. The nitrogen cycle is driven by both chemolithotrophic and chemoorganotrophic bacteria, organisms that produce and consume organic carbon, respectively. We considered the microbiology of biogeochemical cycles and their coupled nature in Chapters 14 and 15 and will revisit this theme in more detail in Chapter 21.

Check Your Understanding

- How does a microbial guild differ from a microbial community?
- What is a biogeochemical cycle? Give an example based on sulfur. Why are biogeochemical cycles also called nutrient cycles?

II • The Microbial Environment

Being so small, microbes directly experience only a tiny portion of their environment. Microbial interactions, often as part of attached or layered communities, are based on consumption, generation, and diffusion of nutrients and the products of metabolism.

Microorganisms define the limits of life throughout aquatic and terrestrial environments on our planet. Specific conditions required by a particular organism or group of organisms may be subject to rapid change as a result of inputs to and outputs from their habitat or as a result of microbial activities or physical disturbances. Thus, within one environment there can be multiple habitats, some relatively stable and others changing rapidly over time and space.

20.3 Environments and Microenvironments

Besides living in the common habitats of soil and water, microorganisms thrive in extreme environments and also reside on and within the cells of other organisms. The intimate associations developed between microorganisms and other organisms will be explored in Chapters 23 and 24. Here we focus on terrestrial and aquatic microbial habitats.

The Microorganism, Niches, and the Microenvironment

The habitat in which a microbial community resides is governed by physicochemical conditions that are determined in part by the metabolic activities of the community. For example, the organic material used by one species may have been a metabolic by-product of a second species. Another example is oxygen (O_2), which can become limiting if biological consumption exceeds the rate at which it is supplied.

Because microbes are very small, they directly experience only a tiny local environment; this small space is called their **microenvironment**. For example, for a typical 3- μm rod-shaped bacterium, a distance of 3 mm is equivalent to that which a human would experience over a distance of 2 km! As a consequence of the smallness of microorganisms, the variable metabolic activities of nearby microbes, and the changes in physicochemical conditions over short intervals of time and distance, several microenvironments can exist within a given microbial habitat. The conditions supporting growth within a microenvironment correspond to the general requirements for growth we considered in Chapters 3, 4, and 8.

Ecological theory states that for every organism there exists at least one niche, the *realized niche* (also called the *prime niche*), where it will be most successful. The organism dominates the realized niche but may also inhabit other niches; in other niches it is less ecologically successful than in its realized niche, but it may still be able to compete. The full range of environmental conditions under which an organism can exist is called its *fundamental niche* (we considered the realized and fundamental niche in the context of enrichment culture and isolation in Sections 19.1–19.3). The word “niche” should not be confused with the word “microenvironment” because the microenvironment describes conditions at a specific location and can change rapidly. In other words, the general conditions that describe a specific niche may be transient at many places in a microenvironment.

Figure 20.3 Oxygen microenvironments. Contour map of O_2 concentrations in a small soil particle as determined by a microsensor (◀ Section 19.9). The axes show the dimensions of the particle. The numbers on the contours are percentages of O_2 concentration (air is 21% O_2). Each zone can be considered a different microenvironment.

Another important consequence of microbes being so small is that diffusion often determines the availability of resources. Consider, for example, the distribution of an important microbial nutrient such as O_2 in a soil particle. Microsensors (◀ Section 19.9) can be used to measure oxygen concentrations throughout small soil particles. As shown in the data from an actual microsensor experiment (Figure 20.3), soil particles are not homogeneous in terms of their O_2 content but instead contain many adjacent microenvironments. The outer layer of the soil particle may be fully oxic (21% O_2) while the center, only a very short distance away (in human terms, but of course a great distance from a microbial standpoint), may be anoxic (O_2 -free). The microorganisms near the outer edges consume all of the O_2 before it can diffuse to the center of the particle. Thus, anaerobic organisms could thrive near the center of the particle, microaerophiles (aerobes that require very low oxygen levels) farther out, and obligately aerobic organisms in the outermost region of the particle. Facultatively aerobic bacteria (organisms that can grow either aerobically or anaerobically, ▶ Section 4.16) could be distributed throughout the particle. Nutrient transfer is particularly important in thick assemblages of cells, such as biofilms and microbial mats, and we explore this in Section 20.4.

Physicochemical conditions in a microenvironment are subject to rapid change in both time and space. For example, the O_2 concentrations shown in the soil particle in Figure 20.3 represent “instantaneous” values. Measurements taken in the same particle following a period of intense microbial respiration or disturbance due to wind, rain, or disruption by soil animals could differ dramatically from those shown. During such events certain populations may temporarily dominate the activities in the soil particle and grow to high numbers, while others remain dormant or nearly so. However, if the

microenvironments shown in Figure 20.3 are eventually reestablished, the various microbial activities characteristic of different regions of the soil particle will eventually return as well.

Nutrient Levels and Growth Rates

Resources (Table 20.1) typically enter an ecosystem intermittently. A large pulse of nutrients—for example, an input of leaf litter or the carcass of a dead animal—may be followed by a period of nutrient deprivation. Because of this, microorganisms in nature often face a “feast-or-famine” existence. It is thus common for them to produce storage polymers as reserve materials when resources are abundant and draw upon these reserves in periods of starvation. Examples of storage materials are poly- β -hydroxyalkanoates, polysaccharides, and polyphosphate (◀ Section 2.7).

Extended periods of exponential microbial growth in nature are typically rare, except in certain extreme environments—for example, a hot spring—where conditions and resources may stay optimal indefinitely. Instead, microorganisms typically grow in spurts, linked closely to the availability and types of resources and ideal growth conditions. Because all relevant physicochemical conditions in nature are rarely optimal for microbial growth at the same time, growth rates of microorganisms in nature are usually well below the maximum growth rates recorded in the laboratory. For instance, the generation time of *Escherichia coli* in the intestinal tract of a healthy adult eating at regular intervals is about 12 h (two doublings per day), whereas in pure culture it can grow much faster, with a minimum generation time of about 20 min under optimal conditions. In addition, research-based estimates indicate that most cultured soil bacteria typically grow in nature at less than 1% of the maximal growth rate measured in the laboratory.

These slower growth rates in nature than in laboratory culture reflect the facts that (1) resources and growth conditions (Table 20.1) are frequently suboptimal; (2) the distribution of nutrients throughout the microbial habitat is not uniform; and (3) except in rare instances, microorganisms in nature grow in mixed populations rather than pure culture. An organism that grows rapidly in pure culture may grow much slower in a natural environment where it must compete with other organisms that may be better suited to the resources and growth conditions available.

Microbial Competition and Cooperation

Competition among microorganisms for resources in a habitat may be intense, with the outcome dependent on several factors, including rates of nutrient uptake, inherent metabolic rates, and ultimately, growth rates. A typical habitat contains a mixture of different species (Figures 20.1 and 20.2), with the density of each population dependent on how closely its local environment resembles its realized niche.

Some microbes work together to carry out transformations that neither can accomplish alone—a process called *symbiosis*—and these microbial partnerships are particularly important for anoxic carbon cycling (◀ Section 14.22 and ▶ Section 21.2). Metabolic cooperation can also be seen in the activities of organisms that carry out *complementary* metabolisms. For example, we have previously considered metabolic transformations that are carried out by two distinct groups of organisms, such as those of the nitrifying *Bacteria* and *Archaea* (◀ Sections 14.9, 15.10, and 17.5). Together, these

nitrifiers oxidize ammonia (NH_3) to nitrate (NO_3^-). Because nitrite (NO_2^-), the final product of most ammonia-oxidizing nitrifiers (◀ Section 15.10 and ▶ Section 21.3), is the substrate for the nitrite-oxidizing bacteria, the two groups of organisms often live in tight association within their habitats (◀ Figure 19.13a).

Winogradsky discovered nitrification in 1890 (◀ Section 1.13), but for over one hundred years no organism capable of complete ammonia oxidation was ever discovered. However, some *Nitrospira* species (Bacteria) can oxidize both ammonia and nitrite (◀ Section 15.10), a process that has been coined *comammox*. With the use of molecular tools (Chapter 19) to survey various habitats for comammox bacteria, related organisms have been identified in wetlands, riverbeds, aquifers, lake sediments, and wastewater treatment systems but not in the oceans. In some of these environments, comammox bacteria seem to outnumber classical nitrifying bacteria (species that catalyze only one step in nitrification), whereas in other environments, comammox organisms may be part of the rare biosphere (◀ Section 19.6), low in abundance yet nevertheless ecologically important microbes.

Check Your Understanding

- What characteristics define the realized niche of a particular microorganism?
- Why can many different physiological groups of organisms live in a single habitat?

20.4 Surfaces and Biofilms

Surfaces are important microbial habitats, typically offering microbes greater access to nutrients and protection from predation and physicochemical disturbances. Attachment to a surface also offers cells a means to remain in a favorable habitat, modify the habitat by their own activities, and not be washed away. In addition, flow across a colonized surface increases the flux of nutrients to the surface, providing more resources than are available to planktonic cells (cells that live a floating existence) in the same environment. A surface may be abiotic, such as a particle of organic matter, or provided by another organism. For example, plant root surfaces become heavily colonized by soil bacteria thriving on organic compounds excreted by the plant, as revealed when fluorescent stains such as acridine orange (◀ Section 19.4) are used on natural samples (Figure 20.4a).

Virtually any natural or artificial surface exposed to microorganisms will be colonized. For example, microscope slides have been used as experimental surfaces to which organisms can attach and grow. A slide can be immersed in a microbial habitat, left for a period of time, and then retrieved and examined microscopically (Figure 20.4b). Clusters of a few cells that develop from a single colonizing cell—called *microcolonies*—form readily on such surfaces, much as they do on natural surfaces (Figure 20.4a). Periodic microscopic examination of immersed slides has been used to measure growth rates of attached organisms in nature.

Surface colonization may be sparse, consisting only of microcolonies not visible to the naked eye, or may consist of so many cells that microbial accumulation becomes visible as, for example, in a stagnant toilet bowl. Surface growth can be particularly problematic in a hospital setting where microbial colonization of indwelling devices such as catheters and intravenous lines can cause serious infection (◀ Figure 4.17b). In a few extreme environments that lack

Figure 20.4 Microbial biofilms on surfaces. (a) Fluorescence photomicrograph of a natural microbial community living on plant roots in soil and stained with acridine orange. Note microcolony development. (b) Bacterial microcolonies developing on a microscope slide that was immersed in a river. The bright particles are mineral matter. The short, rod-shaped cells are about 3 μm long. (c) Confocal scanning laser microscopy through a natural biofilm (top view) on a leaf surface. The color of the cells indicates their depth in the biofilm: red, surface; green, 9- μm depth; blue, 18- μm depth. (d) A cross-sectional view of an experimental biofilm composed of cells of *Pseudomonas aeruginosa*. The yellow layer (about 15 μm in depth) contains cells and is stained by a reaction showing activity of the enzyme alkaline phosphatase.

small animal grazers (for example, hot springs), microbial accumulation on a surface can be layered and several centimeters thick. Called *microbial mats* (Section 20.5), such accumulations often contain highly complex yet very stable assemblages of phototrophic, chemolithotrophic, autotrophic, and heterotrophic microbes.

Layered communities can even form where light penetrates the near-surface interior of minerals, such as calcium sulfate (gypsum) crusts in solar salterns. Despite the extremely high salt content of these crystals, they are readily colonized by a community of halophilic phototrophs and heterotrophs (Figure 20.5). The phototrophic components in the gypsum crusts include cyanobacteria (◀ Section 15.3; orange- and green-colored layers in Figure 20.5) and purple sulfur bacteria (◀ Section 15.4, red layer in Figure 20.5). Purple bacteria grow in the deepest layer of the crust because of their need for H_2S (produced by sulfate-reducing bacteria deeper in the crust) and ability to grow at low light intensities.

Biofilms

As bacterial cells grow on surfaces, they commonly form **biofilms**—assemblages of bacterial cells attached to a surface and enclosed in

Figure 20.5 Endolithic microbial biofilm. Section through a submerged calcium sulfate (gypsum) crust that formed in a Guerrero Negro (Baja California, Mexico) crystallizer pond showing layered phototrophic microbial communities. The orange layer just under the crust surface contains the unicellular cyanobacterium *Halotheca*, the green layer a mixture of unicellular and filamentous cyanobacteria, and the red layer purple sulfur bacteria of the genera *Ectothiorhodospira* and *Halochromatium*. Various chemotrophic bacteria are present in each of the layers as well, including sulfate-reducing bacteria, the source of the H_2S that feeds the purple sulfur bacteria.

an adhesive matrix that is the product of excretion by cells and cell death (Figure 20.4c, d). The matrix is typically a mixture of polysaccharides, proteins, and nucleic acids that bind the cells together. Biofilms trap nutrients and help prevent the detachment of cells on dynamic surfaces, such as in flowing systems (Figure 20.6). We examined the basic properties of biofilms in Section 4.9 and genetic and regulatory features of biofilm formation in Section 8.10, and so here we focus on their ecological and medical consequences.

Biofilms typically contain multiple layers of cells embedded in the porous matrix material, and the cells in each layer can be examined by confocal scanning laser microscopy (◀ Section 1.9; Figure 20.4c). Biofilms may contain one or two species or, more commonly, many species of bacteria. The biofilms that form on tooth and soft surfaces of the mouth, for example, contain between 100 and 200 different phylotypes (◀ Section 19.6), including species of both *Bacteria* and *Archaea*; in total, the human mouth is a habitat for at least 700 phylotypes (▶ Sections 24.3 and 25.2). Biofilms are thus functional and growing microbial communities and not just cells trapped in a sticky matrix.

Wherever submerged surfaces are present in natural environments, biofilm growth is almost always more extensive and diverse than the planktonic growth in the liquid above the surface. Biofilms differ from planktonic communities in supporting critical transport and transfer processes, which generally control growth in biofilm environments. For example, if consumption of O_2 by populations near the surface exceeds diffusion of O_2 into deeper regions of the biofilm, the deeper regions will become anoxic, opening up new niches for colonization by obligate anaerobes or facultative aerobes. This is analogous to the depletion of O_2 in the interior of a soil particle that was depicted in Figure 20.3. Hence, different metabolisms can be active in different regions of a biofilm and this broadens the diversity of microbes that can exist there.

Why Bacteria Form Biofilms

At least three reasons have been proposed for the formation of biofilms. First, biofilms are a means of microbial self-defense that increase survival. Biofilms resist physical forces that could otherwise remove cells only weakly attached to a surface. Biofilms also resist phagocytosis by protozoa and cells of the immune system and retard

the penetration of toxic molecules such as antibiotics. These advantages improve the chances for survival of cells in the biofilm. Second, biofilm formation allows cells to remain in a favorable niche. Biofilms attached to nutrient-rich surfaces, such as animal tissues, or to surfaces in flowing systems (Figure 20.6) fix bacterial cells in locations where nutrients may be more abundant or are constantly replenished. Third, biofilms form because they allow bacterial cells to live in close association with each other. This facilitates cell-to-cell communication, offers more opportunities for nutrient and genetic exchange, and in general increases chances for survival.

The fact that biofilms form on virtually any surface capable of supporting bacterial growth suggests that biofilms are the “default” growth mode for bacteria in natural habitats. Planktonic growth, so common in shaken or otherwise mixed laboratory cultures, may thus be an atypical growth mode and the norm only for those bacteria adapted to life at extremely low nutrient concentrations (oligotrophs, Sections 20.9, 20.10, and 20.12). For example, the rocky and pebbly substratum of rivers and streams is an important biofilm habitat, as any hiker attempting to cross over the slippery rocks of a mountain stream is aware. This type of biofilm is in part nourished

(a)

(b)

Figure 20.6 Phototrophic biofilms in rivers and streams. (a) Phototrophic biofilms colonizing the rocky bottom of a stream flowing from the Rhone Glaciers, Switzerland (water is flowing toward the viewer). The striped patterns emerge from microbial growth along different flow paths of the glacial outflow. (b) Cyanobacteria attached to the river rocky substratum form “tower-like” clusters with apical oxygen bubbles forming from high photosynthesis rates within the clusters. The clusters are about 0.5–1 cm high.

by phototrophic algae and cyanobacteria that rapidly colonize newly exposed surfaces (Figure 20.6a).

Although biofilms are known to provide some resistance to grazing, they are not immune to grazing and typically attract high densities of micrograzers, including heterotrophic flagellates, amoebae, and ciliates. These specialized biofilm micrograzers, together with small metazoans called *meiofauna* (rotifers, nematodes, microcrustaceans, oligochaetes, and flies), feed on components of the biofilm. In doing so, they incorporate a significant amount of the carbon fixed by biofilm autotrophs and also remove planktonic cells and organic carbon from the water column. Thus, by existing at the interface between an inert substratum and surface water, river and stream biofilms provide significant ecosystem services by coupling benthic and water column microbial communities and nourishing higher trophic levels in aquatic systems.

Biofilms on Microplastics

In addition to natural surfaces, plastics provide an artificial surface for microbial colonization, and biofilms that develop on plastics can have both beneficial and harmful aspects. Each year humans add millions of metric tons of plastic to the oceans alone. Biodegradation and weathering processes degrade this plastic into small particles and fibers less than 5 mm in diameter called *microplastics* (MPs, Figure 20.7), and the surfaces of MPs get colonized by microbes. On the one hand, the formation of biofilms on these surfaces signals the initial stages of biodegradation and can be considered a good thing. But on the other hand, more than 200 marine organisms are known to ingest microplastics, including zooplankton, fish, seabirds, marine mammals, and benthic invertebrates. Depending on the animal, MPs can cause a variety of health issues including neurotoxicity, DNA damage, reproductive defects, and decreased

filtration rates in filter feeders such as mussels. Unfortunately, biofilm-coated (as opposed to clean) MP may actually escalate this environmental problem.

Surface colonization and biodegradation of plastic by microorganisms is suspected to increase harmful environmental effects by altering the surface chemistry, density, and sinking rates of MPs. In addition, since microbially colonized MPs (Figure 20.7) can be greatly enriched in hydrophobic organic contaminants relative to surrounding seawater, they are also a conduit for the delivery of these adsorbed contaminants to filter-feeding biota. Thus, apart from the possibility that filter feeders may preferentially ingest biofilm-encrusted MPs because of their higher nutritional quality, most studies point to only adverse impacts of MPs on aquatic ecosystems.

Problem Biofilms for Humans

In addition to aquatic systems, biofilms have significant implications in human medicine and commerce. In the body, bacterial cells within a biofilm are protected from attack by the immune system, and antibiotics and other antimicrobial agents often fail to penetrate the biofilm. One of the most clinically and industrially relevant properties of biofilm microbial communities is their inherent tolerance of antibiotics and other antimicrobial chemicals. A given species growing in a biofilm can be up to 1000 times more tolerant of an antimicrobial substance than planktonic cells of the same species. Reasons for this greater tolerance include slower growth rates in biofilms, reduced penetration of antimicrobial substances through the extracellular matrix, and the expression of genes that increase tolerance to stress. This tolerance of antimicrobial substances may explain why biofilms are responsible for many untreatable or difficult-to-treat chronic infections and are also hard to eradicate in industrial systems, such as wastewater plants, where surface growth (fouling) by microbes may impair important processes.

As we saw in earlier chapters, the bacterium *Pseudomonas aeruginosa* forms tenacious biofilms (◀ Sections 4.9 and 8.10 and Figure 4.16), and biofilms of this organism form in the lungs of humans suffering from the genetic disease *cystic fibrosis*. Once in the biofilm state, *P. aeruginosa* is difficult to treat with antibiotics and the biofilm helps the organism persist. *Burkholderia* (previously *Pseudomonas*) *cepacia* is also a threat to those with cystic fibrosis (◀ Section 16.2). Besides cystic fibrosis, biofilms have been implicated in several medical and dental conditions, including periodontal disease, chronic wounds, kidney stones, tuberculosis, Legionnaires' disease, and *Staphylococcus* infections (◀ Figure 4.17b). Medical implants are ideal surfaces for biofilm development. These include both short-term devices, such as urinary catheters, as well as long-term implants, such as artificial joints. It is estimated that 10 million people a year in the United States experience biofilm infections from implants or intrusive medical procedures. Biofilms also explain why routine oral hygiene is so important for maintaining dental health. Dental plaque is a typical biofilm and contains acid-producing bacteria responsible for dental caries (▶ Sections 24.3 and 25.2 and Figures 25.7, 25.8).

Biofilms affect commerce because they can slow the flow of water, oil, or other liquids through pipelines and can accelerate corrosion of the pipes themselves (◀ Figure 1.17). Biofilms also initiate the degradation of submerged objects, such as structural components of offshore oil platforms, boats, and shoreline installations. The safety

Figure 20.7 Biofilm formation on a microplastics particle. Microbial colonization and biofilm formation (arrows) on a polystyrene microplastics particle following immersion for three months in a bog in Germany. This microplastic particle is 3–4 mm in diameter and about 0.1 mm thick.

of drinking water may be compromised by biofilms that develop in water distribution pipes. These biofilms mostly contain harmless microbes, but if pathogens successfully colonize a biofilm, water purification practices (Chapter 22) may fail to kill them. Periodic releases of pathogenic cells can then lead to outbreaks of disease. For example, it is thought that *Vibrio cholerae*, the causative agent of cholera (► Section 33.3), may be propagated in this manner.

Biofilm control is big business, and thus far, only a limited number of tools exist to fight biofilms. Collectively, industries commit huge financial resources to treating pipes and other surfaces to keep them free of biofilms. New antimicrobial agents that can penetrate biofilms, as well as drugs that eliminate biofilm formation by interfering with intercellular communication, are being developed, but at this point, human battles with biofilms continue at a brisk pace.

- Give an example of a medically relevant biofilm that forms in virtually all healthy humans.
- How is it possible for both aerobes and obligate anaerobes to coexist in the same biofilm?

20.5 Microbial Mats

Microbial mats are among the most visibly conspicuous of microbial communities and can be thought of as extremely thick biofilms. Supported by phototrophic or chemolithotrophic bacteria, these layered microbial communities can be several centimeters thick (Figure 20.8a, b). The layers are composed of species of different microbial guilds whose activities are governed by light availability and other resources (Table 20.1). The combination of microbial metabolism and nutrient transport controlled by diffusion results in steep concentration gradients of different microbial nutrients and metabolites, creating unique niches at different depth intervals in the mats. The most abundant and

versatile phototrophic mat builders are filamentous cyanobacteria, which are oxygenic phototrophs and many of which tolerate extreme environmental conditions. For example, some species of cyanobacteria grow in waters as hot as 73°C or as cold as 0°C, and others tolerate salinities in excess of 12% and pH values as high as 10.

Cyanobacterial Mats

Cyanobacterial mats (Figure 20.8a, b) are complete microbial ecosystems, containing large numbers of **primary producers** (cyanobacteria and other phototrophic bacteria) that use light energy to synthesize new organic material from CO₂. These along with populations of consumers in the mat community mediate all key nutrient cycles.

Microbial mats have existed for over 3.5 billion years (stromatolites, ◀ Section 13.2 and Figure 13.6) but are found today only in aquatic environments where environmental stresses such as high temperatures or high salt concentrations restrict grazing by small animals and insects. Well-studied microbial mats are found in hypersaline solar evaporation basins; such basins have either formed naturally, such as Solar Lake (Sinai, Egypt), or have been constructed for the recovery of sea salt (Figure 20.8a). Layered phototrophic communities also form within the salt crusts of these evaporation basins (Figure 20.5). Because microbial mats are restricted to extreme environments, most are found in remote locations and many are not readily accessible to study. In contrast, however, the cyanobacterial mats that colonize the outflow channels of hot springs in Yellowstone National Park (USA), Iceland, and many other thermal regions in the world are easily accessible and have been widely studied (Figure 20.8b, c).

The chemical and biological structure of a microbial mat can change dramatically during a 24-h period (called a *diel cycle*) as a consequence of light to dark transitions. Using microsensors (◀ Section 19.9) it is possible to measure pH, H₂S, and O₂ repeatedly over a diel cycle in zones in the mat separated vertically by only a few micrometers. During the day, there is intense oxygen production in the cyanobacterial surface layer of microbial mats and active

Figure 20.8 Microbial mats. (a) Mat specimen collected from the bottom of a hypersaline pond at Guerrero Negro, Baja California (Mexico). Most of the bottom of this shallow pond is covered with mats built by the major primary producer, the filamentous cyanobacterium *Microcoleus chthonoplastes*. (b) Microbial mat core from an alkaline Yellowstone National Park (USA) hot spring. The upper (green) layer contains mainly cyanobacteria, while the reddish layers contain anoxygenic phototrophic purple bacteria. (c) Daylight oxygen (O₂), H₂S, and pH profiles through a hot spring mat core such as that shown in part b.

sulfate reduction throughout the lower regions. Near the zone where O_2 and H_2S begin to mix, intense metabolic activity by phototrophic and chemolithotrophic sulfur bacteria may consume these substrates rapidly over very short vertical distances. Detecting the rate of these changes reveals the zones of greatest microbial activity (Figure 20.8c). These gradients disappear at night when photosynthesis stops, and the entire mat turns anoxic as H_2S accumulates. Some mat organisms rely on motility to follow the shifting chemical gradients. For example, sulfur-oxidizing filamentous phototrophic bacteria such as *Chloroflexus* and *Roseiflexus* (◀ Section 15.7) track the up-and-down movement of the O_2 – H_2S interface on a diel basis.

Iron-Rich Microbial Mats

Microbial mats of oxidized iron also form in metal-rich, low-pH environments, such as occurs with the mining of metals (Figure 20.9a; see acid mine drainage, Section 22.2) and in iron-rich hot springs, such as that of Echinus Geyser in Yellowstone National Park (Figure 20.9b). As Fe^{2+} -rich water is exposed to air, iron-oxidizing *Bacteria* and *Archaea* generate a thick mat of oxidized iron. Metagenomic analyses of the Echinus Geyser mat revealed a novel phylum of microaerophilic *Archaea*, provisionally named the *Marsarchaeota* (see Figure 20.16) after the resemblance of their red iron-oxide-rich habitat to the color of Mars. Enrichment cultures of *Marsarchaeota* show large cocci that can oxidize both organic carbon and ferrous

iron. Their heterotrophic capabilities suggest that they receive organic carbon fixed by chemolithotrophs coexisting in these iron-rich mat communities. An example of such a chemolithotroph is *Metallosphaera*, a relative of the sulfur- and iron-oxidizing *Sulfolobus*, a genus of *Archaea* (◀ Section 17.10). We will see in Chapter 22 that acidophilic iron-oxidizing microbes in mining operations can cause considerable environmental damage to both flora and fauna when the acidity and toxic heavy metals their activities release enter aquatic systems.

Chemolithotrophic Microbial Mats

Like iron-rich mats (Figure 20.9), which typically lack phototrophic components and are thus supported by the activities of iron-oxidizing chemolithotrophs, some microbial mats develop from the activities of sulfur-oxidizing chemolithotrophs. The most common of these are mats composed of filamentous sulfur bacteria such as *Beggiatoa* and *Thioploca* species that grow on marine sediment surfaces at the interface between O_2 supplied from oxic overlying waters and H_2S produced by sulfate-reducing bacteria residing in the anoxic sediments. In these dark habitats, photosynthesis cannot occur and so the bacteria oxidize H_2S to yield energy and support autotrophy (◀ Sections 14.7 and 15.12).

Chemolithotrophic mats composed of sulfur-oxidizing *Thioploca* species on sediments of the Chilean and Peruvian continental shelf are thought to be the most extensive microbial mats of any type on Earth (Figure 20.10). The bottom waters near the sediments in this region of the Pacific Ocean are oxygen-depleted (an oxygen minimum zone, Section 20.10) but contain significant levels (about $25\ \mu M$) of nitrate (NO_3^-). *Thioploca* (◀ Figure 15.32b) can oxidize sulfide anaerobically with nitrate as electron acceptor and has evolved a remarkable strategy to bridge these spatially separated resources—nitrate in the overlying water and sulfide in the sediments. *Thioploca* cells contain large internal vacuoles that can concentrate nitrate from the surrounding water to levels as high as 0.5 M. To do this, they migrate upward from the sediments by gliding motility (◀ Section 2.10) and charge their vacuoles with NO_3^- (Figure 20.10a, b). They then return into the anoxic sediment (gliding at speeds of 3–5 mm per hour) to use their stored NO_3^- as an electron acceptor for H_2S oxidation.

The physical and biological structures of both biofilms and microbial mats are determined by metabolic interactions among the microbes within them and the diffusion of nutrients. Thus, as biofilms form on a surface they become increasingly more complex, and in so doing generate new niches for organisms of differing physiologies. This diversity reaches a maximum in mature microbial mats (Figure 20.8a, b), as molecular community sampling (◀ Section 19.6) has shown these structures to be among the most complex microbial communities yet discovered.

Check Your Understanding

- What is a microbial mat, and what major nutrient changes occur in phototrophic mats during a diel cycle?
- How would motile aerobic bacteria in a microbial mat respond to changing O_2 concentrations over a diel cycle?
- What is the strategy used by *Thioploca* to oxidize sulfide in anoxic regions below the surface of marine sediments?

Andreas Teske and Markus Huetzel

Figure 20.10 *Thioploca* mats. (a, c) Filaments of the large sulfur-oxidizing chemolithotroph *Thioploca* extend into the water above the sediment (87-m depth) in the Bay of Concepción off the Chilean coast. (b) *Thioploca* form bundles of 10 to 20 filaments (trichomes) held together by a gelatinous sheath, each bundle approximately 1.5 mm in diameter and 10–15 cm in length. Two species of *Thioploca* commonly inhabit the same bundle: *T. chileae*, about 20 μm in diameter, and *T. araucae*, about 40 μm in diameter. Individual trichomes glide independently within the sheaths and can extend up to 3 cm into the water.

III • Terrestrial Environments

Terrestrial environments range from wet to dry, warm to cold, alkaline to acidic, oxic to anoxic, and nutrient-rich to nutrient-poor. These characteristics control the diversity and activity of microorganisms that inhabit the terrestrial environments found on Earth.

Extensive microbial habitats exist in two terrestrial environments on Earth: surface soils and the deep subsurface. We cover these microbial habitats in the following three sections, the first two on soils and the third one on the subsurface. We consider the basic characteristics of each habitat, explore their microbial diversity, and discuss reasons why the microbes that are present in each habitat may be well suited to their environment.

20.6 Soils: General Properties

The word *soil* refers to the loose outer material of Earth's surface, a layer distinct from the bedrock that lies underneath (Figure 20.11). Soil develops over long periods through complex interactions among the parent geological materials (rock, sand, glacial drift materials, and so on), the topography, climate, and the presence and activities of living organisms.

Soils can be divided into two broad groups: *Mineral soils* are derived from the weathering of rock and other inorganic materials, and *organic soils* are derived from sedimentation in bogs and marshes. Most soils are a mixture of these two basic types. Although mineral soils, which are the primary focus of this section, predominate in most terrestrial environments, there is increasing interest in the role that organic soils play in carbon storage. A detailed understanding of carbon storage (sinks) and sources (such as release of CO_2) is of great relevance to the science of climate change. The carbon cycle is a major focus of Chapter 21.

Soil Composition

Vegetated soils have at least four components. These include (1) *inorganic mineral matter*, typically 40% or so of the soil volume; (2) *organic matter*, usually about 5%; (3) *air and water*, roughly 50%; and (4) *microorganisms and macroorganisms*, about 5%. Particles of various sizes are present in soil. Soil scientists classify soil particles on the basis of size: Those in the range of 0.1–2 mm in diameter are called *sand*, those between 0.002 and 0.1 mm *silt*, and those less than 0.002 mm *clay*. Different textural classes of soil are then given names such as “sandy clay” or “silty clay” based on the percentages of sand, silt, and clay they contain. A soil in which no one particle size dominates is called a *loam*.

Soils are categorized based on their depth in a soil profile, and the absolute depths vary from soil to soil. In a typical mineral soil the O horizon (“O” for “organic”) (Figure 20.11a) is the uppermost layer and is dominated by decomposing organic matter; because of this, vast numbers (as high as $10^{10}/\text{g}$) of microbial cells are often present here. The O horizon segues into the “A” horizon, the soil layer commonly referred to as “topsoil,” which is also organic-rich and extends anywhere from a few centimeters to about 50 cm from the surface, depending on a soil's structural characteristics. The “B” horizon, called “subsoil,” can extend over a meter below the A horizon and is rich in iron- and aluminum-containing clay minerals and thus red/brown in color (Figure 20.11b). Plant roots, especially tree roots, often extend into the B horizon. The “C” horizon, also called “parent material,” transitions into underlying bedrock and can extend for several meters from the surface.

The organic content of a soil is typically inversely related to depth, with the organic-rich O–A horizons transitioning into the more organic carbon-depleted B and nearly organic carbon-free C horizons (Figure 20.11a). Organic matter content of a soil varies with the type, but in the soil shown in Figure 20.11b (a soil that the United States Department of Agriculture would classify as an “alfisol”), values of organic carbon as high as 5% can be present in the O–A horizons; values drop to less than 1% in the B horizon and less than 0.25% beneath this (Figure 20.11a). The nitrogen and phosphorus

Figure 20.11 Soil. (a) Profile of a mature fertile soil. The soil horizons are zones defined by soil scientists, and the graph to the left shows approximate levels of organic carbon in different soil horizons. (b) Photo of a soil profile, showing O, A, and B horizons. This soil from Carbondale, Illinois (USA), is rich in clay and very compact. Such soils are not as well drained as those rich in sand. Note the clear color delineation between the organic-rich A horizon and the less-organic-rich B horizon.

content of soils follows a similar pattern to that of carbon, reflecting the fact that the bulk of these key nutrients are tied up in decaying plants and animals and in microbes, both dead and alive.

Soil Formation

Physical, chemical, and biological processes all contribute to the formation of soil. An examination of almost any exposed rock reveals the presence of algae, lichens, or mosses. These organisms are phototrophic and produce organic matter, which supports the growth of chemoorganotrophic bacteria and fungi. More complex chemoorganotrophic communities composed of *Bacteria*, *Archaea*, and eukaryotes then develop as the extent of the earlier colonizing organisms increases. Carbon dioxide produced during respiration becomes dissolved in water to form carbonic acid (H_2CO_3), which slowly dissolves the rock, especially rocks containing limestone (CaCO_3). In addition, many chemoorganotrophs excrete organic acids, which also promote the dissolution of rock into smaller particles.

Freezing, thawing, and other physical processes assist in soil formation by forming cracks in the rocks. As the particles generated combine with organic matter, a crude soil forms in these crevices, providing sites needed for pioneering plants to become established. The plant roots penetrate farther into the crevices, further fragmenting the rock; the excretions of the roots promote development in the **rhizosphere** (the soil that surrounds plant roots and receives plant secretions) of high microbial cell abundance (Figure 20.4a). When the plants die, their remains are added to the soil and become nutrients for more extensive microbial development. Minerals are rendered soluble, and as water percolates, it carries some of these substances deeper into the soil.

As weathering proceeds, the soil increases in depth and becomes able to support the development of larger plants and small trees. Soil animals such as earthworms colonize the soil and play an important role in keeping the upper layers of the soil mixed and aerated. Eventually, the movement of materials downward results in the *soil profile* (Figure 20.11). The rate of development of a typical soil profile depends on climatic and other factors, but it can take hundreds to thousands of years from bare rock to fertile soil.

Water Availability: Vegetated and Dryland Soils as Microbial Habitats

The limiting nutrients in soils are often inorganic, such as phosphorus and nitrogen compounds, key components of several classes of macromolecules. Another major factor affecting microbial activity in soil is the availability of water, and we have previously emphasized the importance of water for microbial growth (Section 4.15).

Water is a highly variable component of soil, and a soil's water content depends on soil composition, rainfall, drainage, and plant cover. Water is held in the soil in two ways—by adsorption onto surfaces or as free water in thin sheets or films between soil particles (Figure 20.12). The water present in soils has materials dissolved in it, and the mixture is called the *soil solution*. In well-drained soils, air penetrates readily, and the oxygen concentration of the soil solution can be high, similar to that of the soil surface. In waterlogged soils, however, the only oxygen present is that dissolved in water, and this can be rapidly consumed by the resident microbiota. Such soils then become anoxic, and, as described for freshwater environments (Section 20.9), show profound changes in their biological activities.

Figure 20.12 A soil microbial habitat. Very few microorganisms are free in the soil solution; most of them reside in microcolonies attached to the soil particles. Note the relative size differences among sand, clay, and silt particles.

There is also water in the larger channels in soil, where bulk flow is important for rapid transport of microorganisms and their substrates and products.

Arid Soils

The greatest microbial activity in soils is in the organic-rich surface layers in and around the rhizosphere (Figure 20.4a). However, some soils are so dry that plant coverage is greatly limited, and only special microbial communities can thrive. These are *arid soils*, and approximately 35% of Earth's landmass is permanently or

seasonally arid. Aridity can be defined by the *aridity index*, expressed as the ratio of precipitation to potential evapotranspiration (P/PET). Evapotranspiration is the sum of water loss through evaporation and plant transpiration. A region is deemed arid if there is a P/PET of less than 1; that is, water entering through precipitation (and fog and dew) is less than that lost through evapotranspiration.

Arid soils are among the most extreme environments on Earth, with temperature highs in excess of 60°C and lows of −24°C, high insolation (exposure to solar rays), and low water activity (◀ Section 4.15). Although arid regions are typically nearly devoid of leafy plants, they sustain important microbial communities that assemble in and stabilize soil near the surface and reside within and on the surfaces of rocks (◀ Section 19.8 and Figure 19.27). The dominant microorganisms present in these carbon-limited environments are cyanobacteria, with lesser numbers of green algae, fungi, heterotrophic bacteria, lichens, and mosses.

Dryland microbial habitats include *biological soil crusts* (BSCs) (Figure 20.13), ventral surfaces of translucent stones (*hypolithic* colonists), exposed rock surfaces (*epilithic* colonists), and the interior pore spaces, cracks, and fissures of rocks or minerals (*endolithic* colonists; ▶ Figure 18.35 and Figure 20.5). The soil crusts are dominated by the filamentous cyanobacterium *Microcoleus* (Figure 20.13b, c; ▶ Figure 19.27), whereas coccoid *Chroococcidiopsis* species are the predominant endolithic population. The rock colonists play an important role in weathering and soil formation; here we primarily consider the BSC communities.

The BSC functions in soil stabilization of desert ecosystems. Stabilization is critical because of the very slow rate of desert soil formation (<1 cm per 1000 years). Here, the *Microcoleus* and fungi provide soil cohesion, which is further stabilized aboveground by lichens and mosses when present. Importantly, this microbial

Figure 20.13 Biological soil crust (BSC). (a) BSC on the Colorado Plateau shown adjacent to lighter, disturbed soils. (b, c) Scanning electron micrographs of filamentous cyanobacteria (*Microcoleus* species) that bind sand grains together with their sheath material (▶ Figure 19.27). The sand grains in part b are about 100 μm in diameter and the filaments in part c about 5 μm in diameter.

network functions to virtually eliminate soil erosion from wind and water. The BSCs are major determinants of water infiltration and influence local hydrological cycles and water availability to vegetation. Remarkably, when moisture and temperature conditions are optimal, the photosynthetic rates of BSC are comparable to those of vascular plant leaves. In soil crusts dominated by *Microcoleus*, nitrogen-fixing bacteria (◀ Sections 8.9, 3.12, and 15.3) provide most of the nitrogen, and much of the fixed nitrogen is released immediately and made available to *Microcoleus* and other soil biota (◀ Section 19.8). To respond to variability in moisture conditions, desert soil microbial communities have higher relative abundances of genes encoding osmoregulation and dormancy functions; this reflects their adaptation to the extremes in water availability they experience, from rarely very wet to usually dry or even arid.

The disruption of BSCs is a major contributor to *desertification*, a process exacerbated by climate change and human activities. Dust storms resulting from BSC destruction reduce soil fertility, and when heavy dust is deposited on nearby snowfields it accelerates melt and evapotranspiration rates, thereby reducing freshwater inputs to rivers. Once compromised, soil crusts have recovery times varying from 15 to 50 years. Given the expansive terrestrial presence of BSCs, their importance to human and ecosystem function, and the projected increase in aridity associated with climate change (▶ Section 21.9), a better understanding of BSC formation and the rehabilitation of compromised BSCs is important for a healthy planet Earth. In this connection, important new understanding of the metabolic interactions among the microbes that sustain these critical communities is emerging from the new research area of metabolomics (◀ Section 19.8, subsection Utility of Metabolomics: An Environmental Case Study of Biocrusts). As we saw in this section, biocrusts contain both producer and consumer microbes, and the exchange of nutrients between these two groups is extensive (◀ Figure 19.28), bordering on what could be called a symbiosis.

With this brief background on soils, we next consider soil microbial diversity. Although some microbial eukaryotes reside in soils, our focus will be on prokaryotic cells because these are present in soils in highest numbers and greatest diversity.

Check Your Understanding

- What four components make up a typical vegetated soil?
- Which region of soil is the most microbially active? What are important sources and types of carbon in soil?
- Why is the cyanobacterium *Microcoleus* important in arid soils?

20.7 Prokaryotic Diversity in Soils

As we saw in Figure 20.3, even a single soil particle can contain many different microenvironments, and as a consequence, soils typically support the growth of several physiological types of microbes. To examine soil particles directly for microbes, fluorescence microscopes are often used, the organisms in the soil having been previously stained with a fluorescent dye. To visualize a specific microorganism or groups of related microorganisms in a soil particle, staining methods with fluorescent gene probes (including FISH), are used (◀ Section 19.5). Microorganisms can also be observed on soil surfaces directly by scanning electron microscopy (Figure 20.13b, c).

We learned in Chapter 19 that sequence analyses of 16S ribosomal RNA (rRNA) genes obtained from the environment are commonly used as a measure of bacterial and archaeal diversity (◀ Section 19.6). As yet, no natural communities have been so thoroughly characterized by these techniques that *all* resident species have been identified. However, within limits, the method is widely considered to be a valid measure of microbial diversity and avoids the more serious problems of enrichment bias that plague culture-dependent diversity studies (◀ Section 19.1).

Here and in later sections of this chapter we present “phylogenetic snapshots” of major microbial habitats, with the goal of emphasizing trends, patterns, and ecological rationales rather than comprehensive and exhaustive surveys. And importantly, it should be kept in mind when viewing these phylogenetic summaries that the proportions of each group shown in the diagrams reflect the *diversity* of that group (expressed as a fraction of the whole) and not necessarily the *abundance* of the group. Indeed, some environments contain highly diverse groups that are few in number, and vice versa.

Soil Bacterial and Archaeal Diversity

Molecular community sampling of a typical vegetated surface soil has shown typically *thousands* of different species of *Bacteria* and *Archaea* in a single gram of soil, likely reflecting the numerous microenvironments (Figure 20.3) present there. A “species” is defined here as a 16S rRNA gene sequence obtained from a microbial community that differs from all other sequences by more than 3% (◀ Section 13.12). Such an environmental sequence is called a *phylotype* (also commonly called an *operational taxonomic unit*, or OTU).

Besides very large species numbers, soil microbial diversity studies have also showed that diversity varies with soil type and geographical location. For example, analysis of an Alaska forest soil, an Oklahoma prairie soil, and a Minnesota farm soil (all sites in the USA) revealed approximately 5000, 3700, and 2000 different phylotypes, respectively. The Alaska and Minnesota soils showed similar distributions at the phylum level of taxonomy (for example, *Proteobacteria*, *Acidobacteria*, *Bacteroidetes*, *Actinobacteria*, *Verrucomicrobia*, and *Planctomycetes*) but shared only about 20% of their species in common. This indicates that although the *proportions* of the dominant phyla in different soils are relatively constant, the *actual species present* within a phylum may vary considerably between different soils. In addition, lower bacterial diversity was observed in the farm soil than the Alaska soil, an indication that modern intensive agricultural practices that rely heavily on fertilization, low plant diversity, and the chemical suppression of unwanted plants and animals, reduce bacterial diversity.

Figure 20.14 shows a diversity snapshot of prokaryotic soil communities based on pooled 16S rRNA sequence data taken from several soils. As can be seen, *Proteobacteria* (Chapters 15 and 16) make up nearly half of the total phylotypes recovered, with all major subgroups except for *Epsilonproteobacteria* well represented. The dominance of *Proteobacteria* in soils is not surprising because the enormous phylogenetic diversity shown by this group is reflected in their enormous metabolic diversity. Phototrophy, chemolithotrophy, and a broad range of chemorganotrophic metabolisms—both aerobic and anaerobic—are hallmarks of the *Proteobacteria* (Chapters 14–16). Many pseudomonads, for example, are genetically equipped to use any of over

Figure 20.14 Soil bacterial and archaeal diversity. The results are pooled analyses from several studies of the 16S rRNA gene content of soil environments. Many of these groups are covered in Chapters 15 and 16 (*Bacteria*) or 17 (*Archaea*). For *Proteobacteria* and *Bacteroidetes*, major subgroups are indicated. Note high species richness as indicated by the large proportion of the total community composed of unclassified and minor bacterial groups. Also note the relatively low proportion of the total prokaryotic soil diversity represented by *Archaea*. Data assembled and analyzed by Nicolas Pinel.

100 different organic compounds as carbon and energy sources, a logical metabolic strategy for thriving in soils where the timing and nature of organic inputs can be highly variable. Likewise, many species of *Rhizobiales* can fix N_2 , others specialize in the use of C_1 compounds, and some are even chemolithotrophic or phototrophic, all metabolisms that can be supported in surface soils. In short, the diversity and abundance of *Proteobacteria* in soils is no surprise.

Acidobacteria (◀ Section 16.21) and *Bacteroidetes* (◀ Sections 16.13 and 16.14) are also diverse groups in soil (Figure 20.14), whereas *Actinobacteria* and *Firmicutes* are less so. Although relatively few species of *Acidobacteria* have been cultured, many that have are acid-tolerant and mostly aerobic chemoorganotrophs that collectively use a variety of organic compounds, including plant-derived aromatic compounds, sugars, and polymers common in soils, such as cellulose, xylan, and chitin. Metagenomic analyses (◀ Sections 10.7 and 19.8) are broadening our understanding of *Acidobacteria* metabolic diversity.

Such studies suggest that in addition to a known capacity of some *Acidobacteria* to grow by anaerobic respiration with ferric iron (Fe^{3+}) as electron acceptor (◀ Section 14.13), other species can reduce nitrite, nitric oxide, sulfate, and sulfite (◀ Sections 14.10–14.12). Such capacities should serve these organisms well in soils transitioning from oxic to anoxic conditions. Similar to the *Acidobacteria*, the major groups of soil *Bacteroidetes* (*Sphingobacteria* and *Flavobacteria*) are chemoorganotrophs specialized in the use of complex soil polysaccharides (◀ Section 16.14). Their abilities to hydrolyze these polymers—which are common in soil—and use the monomers generated as electron donors in energy metabolism makes these groups ideally suited to a soil habitat.

In the case of soils, diversity also reflects abundance. *Proteobacteria* are the most abundant bacteria in most soils followed by *Acidobacteria* and *Actinobacteria*. *Bacteroidetes*, although a highly diverse group in most soils, is not very abundant, averaging about

the same number of cells per gram of soil as the *Chloroflexi*, a group much less diverse than the *Bacteroidetes* (Figure 20.14).

In contrast to *Bacteria*, the diversity of *Archaea* in soil is minimal, with relatively few sequences that group with only two major phyla—the *Euryarchaeota* and the *Thaumarchaeota*—commonly observed. But low diversity does not necessarily mean low cell numbers; an archaeal assemblage comprising a small slice of overall diversity can have major biogeochemical importance. For example, species of *Thaumarchaeota*, comprised solely of ammonia-oxidizing *Archaea* (◀ Section 17.5), are a small part of overall soil diversity (Figure 20.14) but are present in relatively high abundance, greatly outnumbering the ammonia-oxidizing *Bacteria* in the *Nitrosomonadales* (*Betaproteobacteria*). Indeed, *Thaumarchaeota*, with their characteristic ability to oxidize ammonia present in trace amounts, are now thought to be responsible for the majority of nitrification in most soils (◀ Section 14.9). Nevertheless, when comparing entire domains, the abundance of *Bacteria* in most soils greatly exceeds that of *Archaea* by several orders of magnitude.

Polluted Soils

A similar study to that shown in Figure 20.14 but performed on hydrocarbon-polluted soil showed that the general taxonomic makeup of polluted and unpolluted soils is similar: *Proteobacteria* comprise the largest fraction in both soil types, followed by significant representation of *Acidobacteria*, *Bacteroidetes*, *Actinobacteria*, and *Firmicutes*. However, there was a significant shift in fractional representation of these taxa in the two soils. Polluted soils are enriched in *Actinobacteria*, *Gammaproteobacteria*, and *Euryarchaeota* but diminished in *Bacteroidetes*, *Acidobacteria*, and unclassified *Bacteria* relative to unpolluted soils. Hydrocarbon-polluted soils contained a single dominant *Bacteroidetes* phylotype, whereas unpolluted soils contained several phylotypes of *Bacteroidetes* (Figure 20.14). Notably, *Thaumarchaeota* are absent from all surveys of hydrocarbon-polluted soils, suggesting that hydrocarbon pollutants suppress ammonia-oxidizing *Thaumarchaeota*.

Although the functional significance of the observed diversity of microbial communities in polluted versus unpolluted soils is unknown, the shifts observed signal that the two soils will likely differ in their capacity to process carbon and nitrogen and to carry out other important nutrient cycling events. However, despite this lack of a functional connection, different 16S rRNA gene surveys of soils agree on two things: (1) undisturbed, unpolluted soils support very high prokaryotic diversity, and (2) soil perturbations trigger measurable shifts in community composition toward species that are more competitive in the disturbed soil and are accompanied by an overall reduction in diversity.

Climate and Disturbance Effects on Soil Microbes

The importance of understanding the diversity of microbes and microbial processes in soils has been highlighted by the concern about the impact climate change will have on soil systems, including the microbial response to higher temperatures, rainfall patterns, and the rapid changes taking place in land use. From what is known today of microbial and metabolic diversity, climate change will almost certainly impact biogeochemical cycles, and such functional understanding is essential for predicting whether soils will be a sink or a source of atmospheric CO₂.

Since cultured diversity from soil is still but a fraction of the diversity that is known to be there, metagenomic analyses combined with

16S rRNA surveys are relied upon to provide insight into the effects of climate and land use changes. For example, a recent metagenomic study of the consequences of deforestation in the Brazilian Amazon revealed distinct microbial community shifts between pasturelands and adjacent rain forests. *Acidobacteria* (Figure 20.14) were associated exclusively with pasture soils. In contrast, the candidate division *Rokubacteria* was almost exclusively associated with rain forest soils and displayed distinct metabolic properties, using carbon sources ranging from methane to complex hydrocarbons.

This and other examples of shifts in microbial diversity due to land use changes illustrate the fact that microbial diversity in any environment is a dynamic entity and will change—sometimes dramatically—in response to environmental changes in conditions and resources. Since large-scale changes in microbial activities typically follow large-scale shifts in diversity, future soil problems associated with climate change and land disturbances could be significant. And, since humans rely on soil one way or the other for the majority of their food, it is easy to see why studying the effect on microbes of climate and land changes is an urgent and important problem that will require more intensive cultivation and metagenomic surveys.

Check Your Understanding

- How might a microbial group having relatively minor representation in soil diversity still have major biogeochemical importance?
- Which three phyla of *Bacteria* dominate the bacterial diversity of soils? Which phylum of *Archaea* dominates and how does it obtain energy?
- Why should humans be concerned if a climate-induced major shift in soil microbial diversity occurred?

20.8 The Terrestrial Subsurface

Surface soils and subsurface terrestrial environments provide quite different habitats for microorganisms. Microbes in vegetated soils benefit from relatively high levels of nutrients because of their association with growing plants, periodic large inputs of nutrients from dead plants and animals, and inputs of moisture from rain events. By contrast, microbes living below the C horizon (Figure 20.11) have few if any of these advantages. Because of nutrient limitations, microbial diversity and abundance in the deepest terrestrial environments are typically extremely low.

Sampling deep subsurface or marine sediments is expensive and difficult, especially in extracting samples from great depths without contamination from upper subsurface zones. Nevertheless, a number of studies of subsurface soils, deep confined aquifers, and deep marine sediments have been done. Many have focused on the microbial diversity of easily accessible groundwater systems that are within a few hundred meters of the surface. More limited surveys, often requiring more specialized drilling equipment, have examined deep marine sediments and deep confined aquifers.

From research made possible by the development of improved drilling and aseptic sampling technology (Figure 20.15), it is now known that microbial life extends to at least 3000 meters (3 kilometers or 1.9 miles) below the Earth's surface. Results show that the microbial diversity of relatively shallow subsurface areas is similar to that of surface soils; *Proteobacteria*, *Actinobacteria*, *Bacteroidetes*, and

Figure 20.15 Sampling the deep subsurface. (a) Drilling to 600 m in Allendale, South Carolina (USA), for the U.S. Department of Energy (DOE) Deep Subsurface Microbiology Program. Subsurface microbiology is both expensive and challenging from the standpoint of obtaining uncontaminated samples from deep underground. (b) Sampling hot (55°C) fissure water from a depth of 3000 m in the Tau Tona South African gold mine.

Firmicutes generally predominate (Figure 20.14), but their abundances decrease with depth, likely a result of decreasing organic carbon availability (Figure 20.11a). Less highly represented groups, such as *Acidobacteria*, *Verrucomicrobia*, and unclassified lineages, are also commonly encountered. Many unclassified *Bacteria* and *Archaea* affiliate with novel phyla and are extremely small and likely grow as symbionts of other microbes (see Figure 20.17). The only group that occasionally shows increases in relative abundance with depth are the *Firmicutes*, in particular, the *Clostridiales*. These are anaerobic bacteria capable of forming endospores (◀ Sections 2.8 and 16.8) and thus could be expected to survive long periods of dormancy.

Bacteria in the Deep Subsurface

Research on the deepest microbial biosphere has been facilitated by drilling of deep marine sediments and mining and drilling operations that expose aquifer waters in fractured granitic rock at great depths. For example, samples collected from a nearly 3-km-deep gold-mining operation in South Africa (Figure 20.15b) revealed phylotypes of species of *Bacteria* and *Archaea*. A common geochemical feature of deep granitic aquifers is the presence of significant sulfate at depths greater than 1000 meters. The possibility that sulfate respiration could contribute to a subsurface biosphere was confirmed by analysis of DNA extracted from fissure water deep in this mine, showing that a H_2 -oxidizing, sulfate-reducing bacterium (◀ Sections 14.12 and 15.11) was virtually the only bacterium present. Genome analysis of the organism, as yet uncultured but given the provisional name *Desulfuridis audaxviator*, indicated that it should be moderately thermophilic (the aquifer temperature at this depth was approximately 50°C) and should be capable of autotrophic growth using H_2 as the electron donor for anaerobic respiration and CO_2 fixation. In addition, the

organism contained genes encoding nitrogen fixation (◀ Section 3.12), meaning that it should be able to live in an anoxic environment on a diet of a few minerals, CO_2 , SO_4^{2-} , N_2 , and H_2 —a lean diet indeed!

D. audaxviator should be well suited to long-term isolation in the deep subsurface, as would other autotrophic and nitrogen-fixing bacteria that could use H_2 as electron donor. Possible subsurface sources of H_2 include the radiolysis of water by uranium, thorium, and other radioactive elements, and geochemical processes such as the release of H_2 from the oxidation of iron silicate minerals in aquifers. H_2 can satisfy the electron donor needs of bacteria that carry out many different anaerobic respirations, including sulfate reduction, acetogenesis, ferric iron reduction, and methanogenesis (Chapter 14), and examples of all these physiologies have been identified from metagenomic analyses of subsurface materials. Hence, *Bacteria* supported by these physiologies undoubtedly inhabit the subsurface microbial ecosystem along with *D. audaxviator*.

Archaea in the Deep Subsurface

As 16S rRNA sequencing is increasingly complemented by environmental genomics (◀ Sections 19.6 and 19.8), additional novel organisms and metabolisms almost certainly await discovery. Notably, although generally in lower abundance than *Bacteria*, many novel *Archaea* inhabit the terrestrial subsurface and marine sediments (Section 20.15). As one example, an archaeon affiliated with marine anaerobic methane oxidizers (◀ Section 14.16) is associated with sulfate-dependent methane oxidation in some deep aquifer communities. In addition to archaeal species from phyla having cultivated representatives (*Euryarchaeota*, *Crenarchaeota*, *Thaumarchaeota*, Chapter 17), several phyla so far identified only through PCR-based and metagenomic surveys include the *Bathyarchaeota*, the Asgard

group, and several others (Figure 20.16; ◀ Section 17.8). These surveys have also revealed a remarkable diversity of extremely small *Archaea* 0.15–1.2 μm in diameter (Figure 20.17) that contain small genomes (~ 500 –1000 genes) and inhabit the subsurface and other nutrient-depleted environments (see Chapter 1 Explore the Microbial World, “Tiny Cells”). These minute *Archaea* form a single deep evolutionary divergence within the *Archaea* that encompasses multiple phyla called DPANN (a “superphylum,” Figure 20.16). The first described member of DPANN was the hyperthermophile *Nanoarchaeum equitans*, a small parasitic species of limited metabolic capacity that grows in obligate physical association with a host archaeon, *Ignicoccus* (◀ Section 17.6). However, besides the parasitic lifestyle, metagenomics suggest that some DPANN species may be autotrophs and thus less metabolically dependent than *Nanoarchaeum*.

At least two major surprises have emerged from metagenomic studies of the *Bathyarchaeota*. First was the discovery of genomes

Luis Cornell

Figure 20.17 Small *Archaea*. Electron micrographic section of a cell of a small species of *Archaea* inhabiting acid mine drainage (▶ Section 22.2). The small *Archaea* found in this acidic environment is a member of the DPANN superphylum (Figure 20.16). The archaeal cell is approximately 0.4 μm in diameter.

Figure 20.16 Diversity and abundance of subsurface *Archaea*. Phylogeny of archaeal clades found predominantly in the terrestrial and marine deep subsurfaces (this is a consensus tree based on 16S rRNA gene sequences and other conserved marker genes). The novel phyla previously unknown until studies of the deep subsurface are highlighted in light blue. Members of the Asgard superphylum are the closest known relatives of eukaryotic cells (◀ Section 13.4).

from subsurface *Bathyarchaeota* (Figure 20.16) that contained genes homologous to those encoding methanogenesis and the acetyl-CoA pathway (the mechanisms of energy conservation and autotrophy, respectively, in methanogenic *Archaea*, ◀ Sections 14.14 and 14.15). Previously, methanogenesis was thought to be restricted to a single phylum of *Archaea*, the *Euryarchaeota*. Second, genomic analyses indicate that some *Bathyarchaeota* likely oxidize methane and others may oxidize longer-chain hydrocarbons, all under anoxic conditions (◀ Section 14.24). Metagenomics also tells us that some *Bathyarchaeota* are heterotrophs, hydrolyzing peptides as carbon and energy sources or degrading polymers such as lignin, a legacy of ancient buried plants.

Other unusual *Archaea*, such as the Asgard group (◀ Section 17.8; Figure 20.16), have emerged from deep marine subsurface metagenomic analyses. Species in this group appear to be heterotrophs and play a role in carbon degradation in anoxic sediments. Some seem genetically equipped to degrade methane—a large reservoir of which exists in the oceanic subsurface—and other short-chain hydrocarbons, such as butane. As discussed in Section 17.8, there is mounting evidence that the eukaryotic domain of cellular life emerged from within the *Archaea*, specifically the Asgard superphylum. This phylogenetic connection is supported by criteria other than just ribosomal RNA gene sequences, including the fact that Asgard genomes encode several eukaryotic-like proteins, such as actin (◀ Section 2.15). Thus, analysis of the deep subsurface biosphere has not only expanded the known phylogenetic diversity of *Archaea* (Figure 20.16) but has revealed new information about the origin of the eukaryotic cell.

Growth Rates and the Future of Subsurface Microbiology

Bacterial numbers in uncontaminated groundwater vary by several orders of magnitude (10^2 – 10^8 per ml), primarily as a function of dissolved organic carbon content. Measured and estimated generation times for deep subsurface bacteria also vary by orders of

magnitude, from days to centuries, as determined by the physico-chemical environment, the physiology of the resident populations, and nutrient availability. Microbes in the deep subsurface likely originate from sedimentary accumulation of near-surface populations. Increasing nutrient limitation with depth of burial then results in selective death of starving populations, and remaining populations are sustained by organic carbon and other nutrients released from dead cells. Only in scattered regions of higher organic carbon content, such as in ancient coal deposits (Figure 20.41), can higher cell numbers be supported.

The many unanswered questions in subsurface microbiology have encouraged the establishment of permanent science laboratories at great depths in the earth. For example, the Sanford Underground Research Facility in Lead, South Dakota (USA) (2400 m deep), is supported by government and private agencies for research in physics, geology, and microbiology. The International Ocean Discovery Program has probed for microbial populations at great depths below the seafloor. Results thus far have shown *Archaea* and *Bacteria* at depths greater than 2000 m below the seafloor (Section 20.15) and in rocks more than 100 million years old. Although this may sound ancient, such ages are actually relatively young compared with viable bacteria that have been recovered from salt crystals dated to nearly a half billion years old. Obviously, microbial cells can remain viable for enormously long periods of time.

We leave soils and the subsurface now to explore the microbial diversity of aquatic environments in the final part of this chapter. Like terrestrial environments, aquatic environments vary considerably. On the one hand, aquatic environments can be nutrient-rich and highly dynamic ecosystems that support large and diverse microbial populations and a wealth of plants and animals. But on the other hand, some aquatic environments provide the same nutrient limitation problems for microbes as is characteristic of the deep subsurface.

Check Your Understanding

- What are possible sources of biologically available energy in the terrestrial subsurface?
- What is the major environmental factor that controls the abundance and type of cells in the deep subsurface?
- How have metagenomic analyses of the *Bathyarchaeota* and the Asgard group brought new metabolic and evolutionary concepts to the forefront?

IV • Aquatic Environments

Marine and freshwater environments host a tremendous diversity of microorganisms and viruses that infect them. Variations in light intensity, pressure, and nutrient availability, along with the effects of human pollution, greatly influence the activities, abundance, and diversity of aquatic microbes.

Freshwater and marine environments differ in many ways including salinity, average temperature, depth, and nutrient content, but both provide many excellent habitats for microorganisms. In this part of the chapter we focus first on freshwater microbial habitats. We then consider two marine environments: (1) coastal and

open ocean waters, and (2) the deep sea. Much new information is emerging about marine microorganisms from studies using the molecular tools of microbial ecology, especially genetic stains, microbial community sampling, and metagenomics (Chapter 19).

20.9 Freshwaters

Freshwater environments vary significantly in the resources and conditions (Table 20.1) available for microbial growth because some lakes and streams are isolated and nearly pristine while others are highly polluted from agricultural, industrial, or residential runoff. Both oxygen-producing and oxygen-consuming organisms are present in aquatic environments, and the balance between photosynthesis and respiration (Figure 20.2) controls the natural cycles of oxygen, carbon, and other nutrients (nitrogen, phosphorus, metals).

Among microorganisms, oxygenic phototrophs include algae and cyanobacteria, both of which are *primary producers*. These organisms can be either *planktonic* (floating) and distributed throughout the water columns of lakes or *benthic*, meaning they are attached to the bottom or sides of a lake or stream. The activity and diversity of chemoorganotrophic aquatic microbial communities depend to a major extent on primary production, in particular its rates and temporal and spatial distributions. If primary production rates are very high, the resultant excessive organic matter production can lead to bottom-water O₂ depletion from respiration and the development of anoxic conditions. This in turn activates anaerobic metabolisms such as anaerobic respirations and fermentations (Chapter 14).

Oxygen Relationships in Freshwater Lakes

The biological and nutrient structure of lakes is greatly influenced by seasonal changes in physical gradients of temperature and salinity. In many lakes in temperate climates, the water column becomes

Figure 20.18 Development of anoxic conditions in waters of a temperate lake due to summer stratification. The colder bottom waters are more dense and contain H₂S from bacterial sulfate reduction. The thermocline is the zone of rapid temperature transition. As surface waters cool in the fall and early winter, they reach the temperature and density of hypolimnetic waters and sink, displacing bottom waters and effecting lake turnover. Data are from a small freshwater lake in northern Wisconsin (USA).

separated into layers of differing physical and chemical characteristics that constitute a **stratified water column**. During the summer, warmer and less dense surface layers, called the **epilimnion**, are separated from the colder and denser bottom layers (the **hypolimnion**). The **thermocline** is the transition zone from epilimnion to hypolimnion (Figure 20.18).

In the late fall and early winter, lake surface waters become colder and thus more dense than the bottom layers. This, combined with wind-driven mixing, causes the cooled surface water to sink and the lake to “turn over,” mixing surface and bottom waters and their nutrients. The separation of a relatively well-mixed surface layer from a relatively static bottom layer limits the transfer of nutrients between layers until fall turnover once again mixes the water column.

During periods of stratification, transfer between surface and bottom waters is controlled not by mixing but by the much slower process of diffusion. As a result, bottom waters can experience seasonal periods of either low or no dissolved O_2 . Whether a lake actually becomes O_2 -depleted depends on several factors, including the amount of organic matter present and the degree of mixing of the water column. Organic matter that is not consumed in surface layers sinks to the depths and is decomposed by anaerobes (Figure 20.2). Lakes may contain high levels of dissolved organic matter because inorganic nutrients that run off the surrounding land can trigger algal and cyanobacterial blooms; these organisms typically excrete various organic compounds and also release complex organic compounds when they die and decay. The combination of water body stratification during early summer, high organic loading, and limited O_2 transfer results in O_2 depletion of the bottom waters (Figure 20.18), making them unsuitable for aerobic organisms such as plants and animals.

The annual turnover cycle allows the bottom waters of a lake to pass from oxic to anoxic and back to oxic. Microbial activity and community composition is altered with these changes in oxygen content, but other factors that accompany fall turnover of the water column, especially changes in temperature and nutrient levels, govern microbial diversity and activity as well. If organic matter is sparse, as it is in unpolluted lakes or in the open ocean, there may be insufficient substrate available for chemoorganotrophs to consume all the oxygen. The microorganisms that dominate such environments are typically **oligotrophs**, organisms adapted to growth under very dilute conditions (Section 20.12). Alternatively, where currents are strong or there is turbulence because of wind mixing, the water column may be well mixed, and consequently oxygen may be transferred to the deeper layers.

Oxygen levels in rivers and streams are also of interest, especially those that receive inputs of organic matter from urban, agricultural, or industrial pollution. Rivers and streams are typically flowing systems and thus rarely become strongly stratified, but even in a river well mixed by water flow and turbulence, large organic inputs can lead to a marked oxygen deficit from bacterial respiration (Figure 20.19a). As the water moves away from a point source input, for example, from an input of sewage, organic matter is gradually consumed, and the oxygen content returns to previous levels. As in lakes, nutrient inputs to rivers and streams from sewage or other pollutants can trigger massive blooms of cyanobacteria and algae (Figure 20.1) and aquatic plants (Figure 20.19b), thereby diminishing overall water quality and growth conditions for aquatic animals.

(a)

(b)

Figure 20.19 Effect of the input of organic-rich wastewaters into aquatic systems.

(a) In a river, bacterial numbers increase and O_2 levels decrease with a spike of organic matter. The rise in algae and cyanobacteria is a response to inorganic nutrients, especially PO_4^{3-} . (b) Photo of a eutrophic (nutrient-rich) lake, Lake Mendota, Madison, Wisconsin (USA), showing algae, cyanobacteria, and aquatic plants that bloom in response to nutrients from agricultural runoff. (See also Figure 20.1).

Biochemical Oxygen Demand

The microbial oxygen-consuming capacity of a body of water is called its **biochemical oxygen demand (BOD)**. The BOD of water, such as that from a temperate lake, is determined by taking a sample, aerating it well to saturate the water with dissolved O_2 , placing it in a sealed bottle, incubating it in the dark (to prevent photosynthetic oxygen production) for 5 days at $20^\circ C$, and determining the residual oxygen in the water at the end of incubation. A BOD determination gives a measure of the amount of organic material in the water that can be oxidized by the microbes present in the water. As a lake or river recovers from an input of organic matter or from excessive primary production, the initially high BOD becomes lower and is accompanied by a corresponding increase in dissolved oxygen in the ecosystem (Figure 20.19a).

In freshwaters, the oxygen and carbon cycles are linked, with the levels of organic carbon and oxygen being inversely related. In other words, high BOD leads to low dissolved oxygen levels. Anoxic aquatic environments, which are typically rich in organic material, are the end result of respiratory processes that remove dissolved oxygen from the ecosystem, leaving the remaining organic material to be mineralized by organisms employing the anaerobic energy metabolisms previously discussed (Chapter 14). It is also important to recognize the importance of storms, floods, and droughts in determining delivery, transport, and cycling of organic matter and inorganic nutrients in freshwater systems, including streams, rivers, lakes, and reservoirs.

These less predictable but nonetheless important changes also affect microbial productivity, diversity, distribution, and interactions.

A Phylogenetic Snapshot of Freshwater Prokaryotic Diversity

The importance of *Bacteria* and *Archaea* in lakes, streams, and rivers to the production, regeneration, and mobilization of nutrients is well recognized, and, as for soil (Section 20.7), 16S ribosomal RNA gene sequencing has been used as a culture-independent method to identify and quantify phylotypes in aquatic microbial habitats. Since most molecular studies of freshwater systems have explored the diversity in lakes, we focus on lakes here.

Figure 20.20 shows the major prokaryotic groups that inhabit lake surface samples (the epilimnion, Figure 20.18). Five major bacterial phyla are routinely observed: *Proteobacteria*, *Actinobacteria*, *Bacteroidetes*, *Cyanobacteria*, and *Verrucomicrobia*. *Euryarchaeota*, *Crenarchaeota*, and *Thaumarchaeota* are the major *Archaea* present but collectively account for only a small fraction of the total prokaryotic abundance and diversity.

The phylum-level composition of *Bacteria* in lakes shares features in common with both surface soils and the oceans, environments where *Proteobacteria* and *Bacteroidetes* also comprise the greater part of diversity (Figure 20.14 and see Figure 20.31). However, compared with lakes and soils, where *Alpha*- and *Betaproteobacteria* show roughly equivalent diversity, we will see in Section 20.12 that in the oceans, *Alpha*- and *Gammaproteobacteria* predominate and *Betaproteobacteria* are only minor components. *Betaproteobacteria* tend to be fast-growing species that respond quickly to periodic pulses of

organic nutrients (for example, leaf litter) that enter lake systems. By contrast, *Alphaproteobacteria* tend to dominate under the more nutrient-limiting conditions of the open ocean.

In addition to leading in the diversity category, *Proteobacteria* are also the most abundant bacteria in most lake systems, with *Actinobacteria* and *Bacteroidetes* species being significant but in lesser abundance. Interestingly, *Acidobacteria*, major components of both diversity and abundance in soils (Figure 20.14), are but a tiny fraction of bacterial diversity and abundance in freshwater lakes.

With the exception of the *Acidobacteria*, it is likely that a similar rationale exists for why the major bacterial phyla found in soil (Figure 20.14) are also found in freshwater: metabolic diversity. *Proteobacteria* excel in this realm and *Bacteroidetes* are well known for their degradation of various biopolymers and aromatic compounds, such as humic materials. *Actinobacteria* are chemoorganotrophs that can also break down polymers, in particular nucleic acids and proteins. In addition, metagenomic analyses (◀ Section 19.8) have shown that at least some *Actinobacteria* contain genes that encode a bacteriorhodopsin-like protein, similar to that which converts light energy into ATP in extremely halophilic *Archaea* (◀ Section 17.1); thus, these *Actinobacteria* may be phototrophic. Moreover, many anoxygenic phototrophs are *Proteobacteria* (◀ Sections 15.4 and 15.5), and their competitive advantage in freshwaters would also rely on photosynthesis. A rationale for cyanobacteria in overall lake diversity (Figure 20.20) hardly needs mentioning, as oxygenic photosynthesis requires nothing but a few inorganic nutrients, CO₂, and plenty of sunshine. Cyanobacterial abundance can also be quite high in freshwater lakes, especially if the lake receives inputs of key inorganic nutrients such as phosphorus and nitrogen; these nutrients often trigger massive cyanobacterial blooms (Figures 20.1 and 20.19b).

Collectively, the high prokaryotic diversity observed in freshwater lakes (Figure 20.20) reflects the dynamic character of these habitats. Lakes typically receive seasonally variable inputs of endogenous and exogenous nutrients, a pattern that sustains a phylogenetically and metabolically complex community of *Bacteria* and a few groups of *Archaea*.

Figure 20.20 Freshwater lake bacterial and archaeal diversity. Distribution of 16S ribosomal RNA gene sequences by phylum determined from analysis of a collective dataset of 16S genes collected from the epilimnion of several freshwater lakes. Data assembled and analyzed by Nicolas Pinel.

Check Your Understanding

- What is a primary producer? In a freshwater lake, would primary producers such as cyanobacteria more likely reside in the epilimnion or the hypolimnion, and why?
- Will addition of organic matter to a water sample increase or decrease its BOD?
- What factor(s) might account for the prokaryotic diversity of freshwater lakes?

20.10 Oxygen Relationships in the Marine Environment

With the exception of oxygen, nutrients in the open ocean (called the *pelagic zone*) are typically at very low levels compared with lakes and other freshwaters. This is especially true of key inorganic nutrients for phototrophic organisms, such as nitrogen, phosphorus, and iron. In addition, water temperatures in the oceans are cooler and more constant seasonally than those of most freshwater lakes. The activity of marine phototrophs is limited by these factors, and thus

total microbial cell numbers are typically about 10-fold lower in the oceans than in freshwater environments ($\sim 10^6$ /ml versus 10^7 /ml, respectively). These are average numbers, and studies of marine prokaryotic diversity are just beginning to reveal recurrent temporal patterns of diversity and abundance.

Tracking Seasonal Changes in Marine Microbial Composition

The Bermuda Atlantic Time-Series Study has a history of continuous biogeochemical monitoring of ocean waters since the mid-1950s, and since the dawn of the molecular ecology era, it has also incorporated diversity studies of microbial population structure. These studies have revealed three major microbial communities in ocean waters that follow a seasonal pattern: (1) the community corresponding to the spring surface water bloom, consisting of small eukaryotic algae, marine *Actinobacteria*, and two groups of *Alphaproteobacteria*; (2) the summertime community in the upper water column associated with water column stratification, consisting of *Pelagibacter*, *Puniceispirillum*, and two groups of *Gammaproteobacteria*; and (3) the more stable deep-water community, consisting of *Nitrosopumilus*, representatives of the SAR11 group with which the genus *Pelagibacter* (see Figure 20.30) affiliates, a group of *Deltaproteobacteria*, and species of two additional groups related to the *Chloroflexi* and *Fibrobacter*. Except for *Nitrosopumilus* (domain *Archaea*), all other deep-water microbes are *Bacteria* (Chapter 16). In Section 20.11, we will return to a more specific breakdown of prokaryotic cell diversity in the open oceans.

Most pelagic *Bacteria* and *Archaea* are very small cells, a characteristic often seen in organisms that inhabit nutrient-poor (oligotrophic) environments. Smallness is an adaptive feature for nutrient-limited microorganisms in that it requires less energy for cellular maintenance and yields a larger surface-to-volume ratio in the cell (◀ Section 1.3). As a consequence of their oligotrophic lifestyle, the genomes of pelagic microbes typically encode very high-affinity transport systems for acquiring the nutrients they need.

Microbial Activities in Marine Environments and Oxygen Minimum Zones

In pelagic waters there is a lower return of nutrients from the bottom waters to upper waters than in freshwater lakes because the waters do not completely turn over seasonally; thus, average primary productivity in the pelagic photic zone is less than in a lake. However, because the oceans are so large, the collective carbon dioxide sequestration and oxygen production from oceanic photosynthesis are major factors in Earth's carbon balance. Terrestrial runoff, retention of nutrients, and upwelling of nutrient-rich waters combine to support higher populations of phototrophic microorganisms in near-shore waters than in pelagic waters (Figure 20.21); these more productive near-shore waters in turn support higher densities of chemoorganotrophic bacteria and aquatic animals, such as fish and shellfish.

In shallow marine waters such as marine bays and inlets, eutrophication resulting from nutrient inputs can lead to the waters becoming intermittently anoxic from the removal of O_2 by respiration and the production of H_2S by sulfate-reducing bacteria. This can lead to **oxygen minimum zones (OMZs)**, regions of oxygen-depleted waters at intermediate depths, typically in waters between 100 and 1000 m, that extend over wide expanses of the open and

Figure 20.21 Distribution of chlorophyll in the western North Atlantic Ocean as recorded by satellite. The eastern coastline of the United States from the Carolinas to northern Maine is shown in dotted outline. Areas rich in phototrophic plankton are shown in red (chlorophyll concentrations of $>1 \text{ mg/m}^3$); blue and purple areas have lower chlorophyll concentrations ($<0.01 \text{ mg/m}^3$). Note the high primary productivity of coastal areas and the Great Lakes.

coastal ocean (Figure 20.22). These oxygen-depleted regions arise when the respiratory demand for oxygen exceeds oxygen availability, and they are associated with nutrient-rich, highly productive regions. In this way they are similar to the depletion of oxygen caused by agricultural runoff in coastal zones (Figure 20.22). However, OMZs predate human activity and originate naturally in regions of high surface production and little mixing with oxygen-rich water.

The oxygen saturation values of the largest of the OMZs in the eastern Pacific off the coast of Peru are less than 10% of that at the surface, but in some other pelagic waters the values actually reach zero. Because of this, OMZs have been recognized as significant sinks for the loss of fixed nitrogen through denitrification (◀ Section 14.11) and anammox (◀ Section 14.10), and as a significant source of nitrous oxide (N_2O), a potent greenhouse gas (▶ Section 21.9; Figure 20.22). Ongoing studies of OMZs have shown that these regions are expanding, and that their recent expansion is almost certainly associated with global warming. As the oceans absorb more heat, warming of the surface waters increases stratification of near-surface waters and reduces oxygen transfer through mixing to deeper regions. Expansion of the OMZs will favor anaerobic microbial processes at the expense of the aerobic processes that sustain critical oceanic food webs. Ultimately, these changes are expected to impact commercial fisheries.

Oxygen-Depleted Marine Dead Zones and the Deepwater Horizon Catastrophe

An extensive region (6000–8000 square miles) of seasonal oxygen depletion in the Gulf of Mexico is associated with high loads of nitrogen and phosphorus carried in by the Mississippi River from agricultural runoff in the Mississippi Valley. This input triggers

Figure 20.22 Diversity of marine systems and associated microbial metabolic processes. Decreasing electron acceptor availability with depth into the sediment or with increasing distance into an oxygen minimum zone is indicated by red wedges. Sulfate becomes limiting only at greater depths in marine sediments. The indicated metabolic diversity is described in Chapter 14.

excessive oxygen consumption from chemoorganotrophs and the formation of hypoxic (oxygen-depleted) water. This region, called the *Gulf of Mexico Dead Zone*, contributes to the loss and impairment of fish and benthic sea life that sustain major seafood industries in this region. In addition to the chronic degradation of the Gulf of Mexico ecology through agricultural runoff, increased offshore oil

drilling also poses significant environmental risk. A major catastrophe for the Gulf of Mexico was the April 2010 explosion and sinking of the Deepwater Horizon offshore drilling platform; failure to control well pressure resulted in the rupture of the wellhead at a depth of 1.5 km and the release of over 4 million barrels of oil before the well was capped three months later (**Figure 20.23**).

(a)

(b)

Figure 20.23 The Deepwater Horizon oil spill in the Gulf of Mexico. (a) Inferno resulting from the wellhead blowout. (b) NASA Terra satellite image taken on May 24, 2010, of the Gulf of Mexico near New Orleans, Louisiana. A large plume of oil was released at about 1500-m depth, some of which reached the surface where sunlight reflects off of the oil slick (arrows).

This largest marine oil spill ever was unique in that most of the oil was released as a plume at great depths in the water column. Typically, marine oil spills contaminate surface waters, resulting in rapid volatilization and loss to the atmosphere of low-molecular-weight oil components such as naphthalene, ethylbenzene, toluene, and xylene. By contrast, the Deepwater Horizon spill released both low-molecular-weight components *and* natural gas (methane, ethane, propane) deep into the water column. These components comprised about 35% of the hydrocarbon plume that extended across many miles of the Gulf from the surface to depths greater than 800 m (Figure 20.23b) and offered an opportunity for microbiologists to measure the effect of a large input of oil to marine waters.

The microbial response to the Gulf spill was tracked over several months using both culture-based and molecular methods, including 16S ribosomal RNA gene and metagenomic sequencing, and GeoChip microarray analyses (◀ Sections 19.6–19.8). Hydrocarbon-degrading bacteria were already enriched in Gulf waters as a consequence of natural seepage of petroleum and natural gas from sediments in coastal regions rich in petroleum reserves (Figure 20.24). These were hydrocarbon-degrading *Gammaproteobacteria* species related to genera in the *Oceanospirillales* group, and of the genera *Colwellia* and *Cycloclasticus*. Microbial diversity and abundance measurements showed that the initial response to the oil spill in May and June of 2010 was a bloom of these very species, probably because of their ability to catabolize gaseous hydrocarbons released from natural seeps (Figure 20.24). This was confirmed with enrichment cultures (◀ Section 19.1) that grew rapidly when ethane or propane was the substrate. *Colwellia* species also contributed to the degradation of a variety of other hydrocarbons, as indicated by their growth in crude-oil enrichment cultures lacking natural gas and by stable isotope probing experiments (SIP, ▶ Section 19.10) that showed incorporation of ^{13}C benzene. Other oil-degrading *Bacteria*

were detected in the Gulf spill as well. In studies of oil consumption on beach sand, a succession was observed in the microbial community during the course of oil consumption as lighter fractions were consumed and more refractory components remained for specialist organisms to consume.

Although there remains uncertainty about the fate of all the hydrocarbons released during the Deepwater Horizon spill, it appears that the early stimulation of hydrocarbon-degrading bacteria by the more soluble, low-molecular-weight gaseous components in the oil reduced the environmental impact of this immense oil spill. Nevertheless, billions of dollars in losses to commercial fisheries and other human activities in the Gulf of Mexico and significant losses of wildlife and wildlife habitat occurred because of the spill.

Check Your Understanding

- Why are marine prokaryotic cells typically quite small?
- What is an oxygen minimum zone and why is expansion of these zones a problem for marine and global ecology?
- What did the Gulf oil spill tell us about how mixed hydrocarbons are degraded in nature?

20.11 Major Marine Phototrophs

The oceans contain large numbers of phototrophic microbes, including both prokaryotic and eukaryotic oxygenic phototrophs as well as significant numbers of a special group of purple (anoxygenic) phototrophs. We consider these organisms here as a prelude to exploring the marine prokaryotic world in general in Section 20.12.

Primary Productivity: *Prochlorococcus*

Much of the primary productivity in the open oceans, even at significant depths, comes from photosynthesis by **prochlorophytes**, tiny bacterial phototrophs that are phylogenetically cyanobacteria (◀ Section 15.3). However, unlike most cyanobacteria, prochlorophytes do not contain phycobilins, although they do contain chlorophylls *a* and *b*. The organism *Prochlorococcus* is a particularly important primary producer in the marine environment (Figure 20.25). Because *Prochlorococcus* lacks phycobilins, which are the accessory pigments of the cyanobacteria (◀ Section 14.4), dense suspensions of *Prochlorococcus* cells are olive green (as are green algae) rather than the blue-green color of cyanobacteria (compare Figures 20.1c and 20.25).

Prochlorococcus accounts for up to half of the photosynthetic biomass and primary production in the tropical and subtropical regions of the world's oceans, reaching cell densities of 10^5 /ml. A number of strains of *Prochlorococcus* have now been identified in culture, and each inhabits its own depth range in pelagic waters. The different *Prochlorococcus* strains are considered distinct *ecotypes*, genetic variants of a species that differ physiologically and therefore occupy slightly different niches. For example, different *Prochlorococcus* ecotypes photosynthesize at different light intensities (high-light versus low-light ecotypes) and use different inorganic and organic nitrogen and phosphorus sources. *Prochlorococcus* is thus distributed in both surface waters and deeper waters to depths of 200 m, and when an oxygen minimum zone (Section 20.10) is present, *Prochlorococcus* extends into the upper regions of this zone (Figure 20.22). This is

Figure 20.24 Marine petroleum seep. (a) Methane and CO_2 are produced by microbial degradation of marine subsurface oil in the Coal Oil Point seep field and migrate through overlying geological strata to be released 21 m underwater in the Santa Barbara Channel off the California Coast. The bubbles also contain small amounts of additional hydrocarbons and H_2S from sulfate reduction. Continuous release of methane and trace hydrocarbons to the water maintain populations of hydrocarbon-degrading microbes capable of responding to accidental petroleum releases. (b) Approximately half the released methane dissolves into the water and becomes available to the microbial community.

near the bottom of the photic zone where light intensities are very low (see Figure 20.29).

Genome sequences of about a dozen cultured *Prochlorococcus* strains revealed that although each contains about 2000 genes, only about 1100 genes (the core genome, ▶ Section 13.10) are shared by all strains. Each presumptive ecotype contains approximately 200 unique genes, which likely have adaptive significance for growth in the realized niche of that ecotype. This was illustrated in Chapter 19

where we compared the genome of a single cultured *Prochlorococcus* ecotype to metagenome sequences obtained from pelagic waters (▶ Section 19.8 and Figure 19.24).

Single-cell genomics (▶ Section 10.11) of natural *Prochlorococcus* populations have refined our understanding of genetic diversity and the relationship between environmental conditions and the fitness of individual genotypes. These analyses revealed a high degree of fine-scale genetic diversity within the high-light (HL) and low-light (LL) ecotypes. Each ecotype is actually composed of hundreds of subpopulations, each of which is united by a common set of core genes encoding functions that control the interaction of the organism with its environment (e.g., transport functions, oxidative stress responses, and cell surface structure) (Figure 20.26b). However, each subpopulation also contains a small set of genes termed “flexible” genes (ranging from 4 to 14 genes per characterized genome) that vary within that subpopulation. The flexible genes are packaged as “cassettes” localized to highly variable regions (genomic islands) within the *Prochlorococcus* genome (▶ Sections 13.10, 19.8, and Figure 19.24). Variation in flexible gene content contributes to exceptionally high *microdiversity* within natural populations of *Prochlorococcus*, pointing to tremendous versatility in their adaptive response to new niche opportunities. The importance of genotypic variability in sustaining large numbers of this major marine phototroph is shown by seasonal shifts in different genotypes in response to changing light intensity, nutrient availability, and predator populations (Figure 20.26a).

Other Pelagic Oxygenic Phototrophs

In tropical and subtropical oceans, the planktonic filamentous marine cyanobacterium *Trichodesmium* (Figure 20.27a) is a widespread and occasionally abundant phototroph. Cells of *Trichodesmium* form colonies of filaments called puffs. Each puff can contain many hundreds of individual filaments, each filament composed of 20–200

An *Ostreococcus* cell is about 0.7 μm in diameter.

cells. In the Caribbean Sea surface waters, colonies of *Trichodesmium* can approach 100/m³. *Trichodesmium* is a nitrogen-fixing cyanobacterium, and the production of fixed nitrogen by this organism is thought to be an important link in the marine nitrogen cycle. *Trichodesmium* contains phycobilins, absent from prochlorophytes, and thus differs from these organisms in its absorption properties (◀ Section 14.4).

Very small eukaryotic phototrophs also inhabit coastal and pelagic waters, and some of these are among the smallest eukaryotic cells known. Three common genera—*Bathycoccus*, *Micromonas*, and *Ostreococcus*—are so small that they contain only one mitochondrion and one chloroplast per cell (a human cell can have hundreds or even thousands of mitochondria). These genera belong to the family *Prasinophyceae*, a group of green algae that diverged early from other lineages of green algae (◀ Section 18.16). Cells of *Ostreococcus* are cocci that measure only about 0.7 μm in diameter (Figure 20.27b), which is even smaller than a cell of *Escherichia coli*.

Although cells of the eukaryotic *Ostreococcus* and the prokaryotic *Prochlorococcus* are of roughly the same dimensions and they are both oxygenic phototrophs, their genomes are distinct. The genome of *Ostreococcus* is 12.6 Mbp (distributed over 20 chromosomes), which is more than seven times the size of the *Prochlorococcus* genome. Even though this is large relative to cyanobacteria, the *Ostreococcus* genome is unusual for that of a eukaryote in being very gene dense, containing about 8000 genes, and is thought to be near the minimum genome size of a free-living phototrophic eukaryote. By comparison, the genome of a common plant, Japanese rice (*Oryza sativa* subsp. *japonica*), is 420 Mbp and contains about 50,000 genes.

In many marine waters, other small eukaryotic cells are present at about 10⁴/ml. Although many of these are *Ostreococcus* or relatives, some are chemoorganotrophs and some are phototrophs unrelated to *Ostreococcus* that incorporate small amounts of organic matter to supplement their primarily phototrophic lifestyle.

Aerobic Anoxygenic Phototrophs

Besides oxygenic phototrophs, anoxygenic phototrophs are also present in coastal and pelagic marine waters. Like purple anoxygenic phototrophs, these organisms contain bacteriochlorophyll *a* (◀ Sections 14.3, 14.5, 15.4, and 15.5). However, unlike classical purple bacteria that carry out photosynthesis only under anoxic conditions, these anoxygenic phototrophs carry out photosynthetic light reactions only under oxic conditions.

Aerobic anoxygenic phototrophs include bacteria such as *Erythrobacter*, *Roseobacter*, and *Citromicrobium* (Figure 20.28), all genera of *Alphaproteobacteria*

(◀ Section 16.1). Aerobic anoxygenic phototrophs synthesize ATP by photophosphorylation when oxygen is present (which is all of the time in oxic pelagic waters), but they are unable to grow autotrophically and thus rely on organic carbon for their carbon sources (a nutritional condition called *photoheterotrophy*). These organisms thus use the ATP produced by photophosphorylation to supplement their otherwise chemoorganotrophic metabolism.

Surveys have shown that a great diversity of aerobic anoxygenic phototrophs exist in marine waters, especially near-shore waters. Oligotrophic and highly oxic freshwater lakes are also habitats for these interesting phototrophic bacteria. The physiology of aerobic

Figure 20.28 Aerobic anoxygenic phototrophic bacteria. Transmission electron micrograph of negatively stained cells of *Citromicrobium*. Cells of this marine, aerobic anoxygenic phototroph produce bacteriochlorophyll *a* only under oxic conditions and divide by both budding and binary fission, yielding morphologically unusual and irregular-shaped cells.

anoxygenic phototrophs is thus ideal for their illuminated and highly oxic habitats.

Check Your Understanding

- How does *Ostreococcus* differ from *Prochlorococcus*? What do they have in common?
- How does the organism *Prochlorococcus* contribute to both the carbon and oxygen cycles in the oceans?
- How does *Roseobacter* differ from *Prochlorococcus*?

20.12 Pelagic Bacteria and Archaea

Despite vanishingly low nutrient levels, significant numbers of *Bacteria* and *Archaea* live a planktonic existence in pelagic marine waters. Of these, one species in particular has garnered significant attention, a bacterium named *Pelagibacter*.

Distribution and Activity of Archaea and Bacteria in Pelagic Waters

The abundance of prokaryotic cells in the open oceans decreases with depth. In pelagic waters, the photic zone extends to a depth of about 200 m, and within this region cell numbers are the highest. In surface waters, cell numbers average about 10^6 /ml. Below 1000 m, however, total cell numbers fall to between 10^3 and 10^5 /ml. The distribution of *Bacteria* and *Archaea* with depth has been tracked in pelagic waters using fluorescence in situ hybridization (FISH) technology (◀ Section 19.5). Species of *Bacteria* tend to predominate in waters above 1000 m, although cells of *Bacteria* and *Archaea* are found in near-equal abundance in deeper waters (Figure 20.29). Deep-water *Archaea* are almost exclusively species of *Thaumarchaeota* (◀ Section 17.5), and many, perhaps even most, are ammonia-oxidizing chemolithotrophs (◀ Sections 14.9 and 17.5) that play an important role in coupling the marine carbon and nitrogen cycles (Chapter 21). Extrapolating to a global basis using the data in Figure 20.29, it is estimated that 1.3×10^{28} and 3.1×10^{28} cells of *Archaea* and *Bacteria*, respectively, exist in the world's oceans. This means that the oceans contain the largest microbial biomass on Earth's surface.

Pelagic *Bacteria* and *Archaea* are ecologically important because they consume dissolved organic carbon in the oceans, one of the largest pools of usable organic carbon on Earth. These small and free-living planktonic microbes consume about half the total oceanic organic carbon produced from photosynthesis and are responsible for about half of all marine respiration and nutrient regeneration. Planktonic marine microbes thus return organic matter to the marine food web that would otherwise be lost because of the inability of larger marine organisms to take up such diluted organic nutrients. This so-called “secondary production” (primary production being that from photosynthesis) is balanced by cell losses from grazing protists and from virus attack (see Figures 20.32, 20.33, and 20.34). This leads to a near-steady state in which the abundance of prokaryotic cells in the open oceans remains roughly constant over time. But importantly, secondary production allows some of the dissolved organic carbon in seawater to reach larger organisms, including fish, because microbes are eventually passed up the food web by the feeding activities of larger organisms.

Figure 20.29 Distribution of *Archaea* and *Bacteria* in North Pacific Ocean water. (a) Percentage of *Archaea* and *Bacteria* with depth. (b) Approximate absolute numbers of *Archaea* and *Bacteria* per milliliter with depth in the open ocean.

Pelagibacter: The Most Abundant Bacterium

Small planktonic chemoorganotrophic bacteria inhabit pelagic marine waters in numbers of 10^5 – 10^6 cells/ml. The most abundant of these are members of the “SAR11 group” within the *Alphaproteobacteria* (◀ Section 16.1) that includes the genus *Pelagibacter*. Environmental metagenomic studies (◀ Sections 10.7 and 19.8) and cell counts done using FISH (◀ Section 19.5) have revealed a great abundance of SAR11 group organisms in pelagic waters. The total oceanic population of this group is estimated to be about 2.4×10^{28} cells—about three-quarters of all *Bacteria*—making it the most successful microbial group, as reflected by abundance, on the planet. *Pelagibacter* is an oligotroph, an organism that grows best at very low concentrations of nutrients and grows in laboratory culture only up to the densities it is found in nature.

What makes *Pelagibacter* so successful in the open oceans? In part, its success is related to small size. Cells of *Pelagibacter* are small rods with a diameter of only 0.2–0.5 μm and a volume of just 0.01 μm^3 , making cells difficult to resolve with the light microscope but not the electron microscope (Figure 20.30). The resulting high surface-to-volume ratio (◀ Section 1.3 and Figure 1.7) facilitates nutrient transport, increasing substrate concentration and processing rates within the cell. Proteomic analyses (◀ Section 10.9) of *Pelagibacter* have also revealed a high abundance of periplasmic binding proteins (◀ Section 2.2) for soluble nutrients such as phosphate, amino acids, and sugars. Another adaptive feature of *Pelagibacter* is its fairly small genome (1.3 Mbp). Consistent with the proteome analysis,

Daniela Nicastro

Figure 20.30 *Pelagibacter*, the most abundant bacterium in the ocean. Electron micrograph taken by electron tomography, a technique that introduces a three-dimensional effect. A single cell of *Pelagibacter* is about 0.2 μm in diameter.

the genome encodes an unusually high number of ABC-type transport systems—transporters that have an extremely high affinity for their substrates (◀ Section 2.2)—and other enzymes useful for an oligotrophic lifestyle. The *Pelagibacter* genome is also highly “streamlined,” with intergenic spacings averaging only 3 base pairs; such a highly compact genome reduces the cost of replication.

Rhodopsins in Marine Microbes

The *Pelagibacter* genome also contains genes encoding a form of the visual pigment rhodopsin that can convert light energy into ATP. In Section 17.1 we discussed the now well-studied molecule *bacteriorhodopsin*, a light-activated protein complex present in the extreme halophile *Halobacterium* (Archaea). Bacteriorhodopsin functions in ATP synthesis as a simple light-driven proton pump; protons pumped across the membrane by this system fuel ATPase in the membrane, generating ATP (◀ Figure 17.4). The form of rhodopsin in *Pelagibacter* and other pelagic *Bacteria* is structurally similar to bacteriorhodopsin and has been called **proteorhodopsin** (“proteo” referring to *Proteobacteria*). Although proteorhodopsin was first discovered in species of *Proteobacteria*, it is actually fairly widely distributed in *Bacteria*; the system is found in many *Gamma*- and *Alphaproteobacteria*, *Bacteroidetes*, and *Actinobacteria* (all covered in Chapter 16), and also in nonhalophilic species of *Archaea*, such as species of the marine *Euryarchaeota* that inhabit the photic zone. The different variants of proteorhodopsins in marine microbes have absorption properties that reflect changing spectral properties of light at increasing depths in the water column, with near-surface variants absorbing green light and those at greater depths absorbing blue light.

Experiments have shown that proteorhodopsin-containing marine bacteria survive starvation better in the light than in the dark. This indicates that energy-starved cells use light-mediated ATP production to compensate for energy unavailable from carbon respiration when organic carbon levels are low. Proteorhodopsins are thought to exist in ~80% of bacteria in some marine waters and are thus a widespread strategy to supplement the energy metabolism of marine microbes such that they need not rely solely on scarce

organic carbon for their energy needs. Metagenomics has shown that a variant of proteorhodopsin called *heliorhodopsin* is widely distributed among marine *Archaea*, *Bacteria*, and *Eukarya*, many of which were previously unsuspected to sense light. However, unlike the energy-generating proteorhodopsins, heliorhodopsins appear to function only as a photosensor, most likely assisting in cellular positioning at an optimal location in a light field that would benefit light-mediated energy-generating systems, such as rhodopsins or chlorophylls.

A Phylogenetic Snapshot of Marine Bacterial and Archaeal Diversity

Several studies have documented the diversity of planktonic marine *Bacteria* and *Archaea* from sequences of 16S ribosomal RNA genes obtained from seawater. The existence of abundant alphaproteobacterial populations with which *Pelagibacter* is affiliated was first revealed by such methods. Mesophilic *Archaea* subsequently shown to be related to ammonia-oxidizing *Nitrosopumilus maritimus* (◀ Section 17.5) were also first observed using this approach.

Major bacterial groups now recognized as abundant in the ocean include *Alpha*- and *Gammaproteobacteria*, *Cyanobacteria*, *Bacteroidetes*, and to a lesser extent *Marinimicrobia* and *Actinobacteria*; *Firmicutes* are only minor components. Long-term studies of oceanic bacterial and archaeal population dynamics using molecular methods (◀ Section 19.6) have provided an unprecedented view of microbial diversity in marine systems. A six-year seasonal sampling study at a coastal site (near Plymouth, England) is one such example (Figure 20.31). Notably, *Cyanobacteria*, which include the ecologically important and relatively abundant phototroph *Prochlorococcus*, comprise only about 1% of diversity in these coastal waters because of competition from eukaryotic phytoplankton (including diatoms and green algae). In contrast, *Cyanobacteria*—and *Prochlorococcus* in particular—dominate the nutrient-limited open ocean.

Proteobacteria, in particular the alpha and gamma classes, clearly dominate the microbial diversity of the oceans. Many marine *Alpha*- and *Gammaproteobacteria* are chemoorganotrophs that metabolize dimethylsulfoniopropionate (DMSP; ◀ Table 4.6), including the alphaproteobacterium *Ruegeria pomeroyi* and species of the gammaproteobacterial genus *Marinomonas*. DMSP is a soluble organic-sulfur compound produced by marine phytoplankton (microscopic eukaryotic phototrophs) that functions primarily as a compatible solute to control osmotic tension in the cell (◀ Section 4.15). However, much of this DMSP gets excreted, and bacteria degrade it, forming the volatile compound dimethyl sulfide (DMS). This gas has a significant effect on Earth’s climate. As the single most important natural source of sulfur released to the atmosphere, DMS becomes photooxidized to sulfuric acid in the atmosphere, and this promotes water condensation and the formation of clouds. The latter deflect sunlight back into space and help cool our planet (▶ Sections 21.4 and 21.9).

R. pomeroyi is a nonphototrophic member of the *Roseobacter* lineage within the *Rhodobacterales* (◀ Section 16.1), an assemblage that also includes many aerobic purple bacteria (◀ Section 15.5) and composes up to a third of the bacterioplankton in coastal waters and a few percent in open ocean surface waters. *R. pomeroyi* and relatives are often the dominant taxa to develop during blooms of

Figure 20.31 Coastal ocean bacterial and archaeal diversity. The results are pooled analyses of nearly one million 16S ribosomal RNA sequences from seasonal sampling near the coast of Plymouth (United Kingdom) over a six-year period. Many of these groups are covered in Chapters 15 and 16 (*Bacteria*) or 17 (*Archaea*). For *Proteobacteria*, major subgroups are indicated. Note the high proportion of *Alphaproteobacteria* and *Gammaproteobacteria* sequences. Data assembled and analyzed by Nicolas Pinel. Compare the prokaryotic diversity of seawater with that of freshwater shown in Figure 20.20.

DMSP-producing phytoplankton, pointing to the importance of this bacterium in generating DMS and influencing atmospheric chemistry.

As is the case for soil microbial diversity (Figure 20.14), a large group of *Bacteroidetes* species and unclassified and minor bacterial groups are also present in seawater. A major group of marine *Gammaproteobacteria* is the yet-to-be-cultured “SAR86 group.” Although accounting for approximately 10% of the total prokaryotic community in the open oceans’ surface layer, this group is only poorly represented in higher-nutrient coastal waters (Figure 20.31). The candidate bacterial phylum *Marinimicrobia* is widely distributed in the ocean, including coastal and pelagic surface waters, oxygen minimum zones (Figure 20.22), and depths greater than 6000 meters. Metagenomic analysis of this phylum has revealed tremendous flexibility in the use of electron acceptors other than oxygen to support anaerobic respirations, including sulfoxides, nitrous oxide, polysulfides, and nitrate, and some species can oxidize thiosulfate as an electron donor. With the exception of the cyanobacteria, most marine *Bacteria* are likely chemoorganotrophs adapted to extremely low nutrient availability in the open ocean, with some augmenting energy conservation through proteorhodopsin or aerobic anoxygenic phototrophy (Section 20.11).

Archaea in pelagic waters comprise a rather restricted diversity of *Euryarchaeota*, *Crenarchaeota*, and *Thaumarchaeota*, most of which have not yet been brought into laboratory culture. The isolation of *Nitrosopumilus maritimus*, affiliated with the *Thaumarchaeota*, revealed that, although not highly diverse (Figure 20.31), ammonia-oxidizing chemolithotrophic *Archaea* are also among the most abundant marine microbes, comprising 20–40% of all marine prokaryotic cells

beneath the photic zone. Although species of *Euryarchaeota* can also be abundant in the upper ocean, comprising 4–20% of the prokaryotic community in surface waters, none have thus far been cultured. However, based on metagenomic analyses, most encode proteorhodopsin, suggesting they grow primarily as photoheterotrophs.

“Dilution culture” and single cell isolation methods employing very dilute culture media have successfully brought some pelagic microbes into culture (◀ Sections 19.2 and 19.3). It appears that most of these organisms have evolved to grow only at very low nutrient concentrations and very low cell densities (10^5 – 10^6 /ml), so it is either difficult or impossible to generate large amounts of cell material in the laboratory. This limitation renders many of the common tools for measuring cell growth (turbidity or microscopic counts) useless on samples that are not first concentrated. Nevertheless, there have been notable successes with dilution culturing of marine bacteria, and the aforementioned bacterium *Pelagibacter* is perhaps the best example of this (◀ Figure 19.6).

- What important role does the bacterium *Ruegeria pomeroyi* play in the health of our planet?
- Why are dilute culture media used for isolating pelagic microbes?

20.13 Pelagic Marine Viruses

Viruses are found everywhere on and in Earth where cellular life is present (including on and in plants and animals) and are present in some environments in enormous numbers. The number of bacterial and archaeal cells on Earth is far greater than the total number of eukaryotic cells; estimates of total prokaryotic cell numbers are on the order of 10^{29} . However, the number of viruses is even greater than this, an estimated 10^{30} . Thus, one might expect that, despite their small size, viruses would play a major ecological role in nature. Soil, freshwater, Earth's deep subsurface, and microbial mats, among many other habitats, are teeming with microbes and the viruses that feed on them. We focus here on seawater to give a feel for the numbers involved and how viruses interact with their prokaryotic hosts.

Bacteriophages and Archaeal Viruses in Seawater

There are about 10^6 prokaryotic cells/ml of seawater and approximately ten times as many viruses. Although viruses account for most of the total microbes present in seawater in terms of numbers, because of their very small sizes they constitute only about 5% of the total microbial biomass. However, using special fluorescence microscopy techniques, viruses can be visualized in seawater (Figure 20.32). It has been estimated that at least 5% and as many as 50% of the *Bacteria* in seawater are killed by bacteriophages each day, and most of the others are eaten by protozoa. For example, Syn5 is a bacteriophage that attacks and lyses *Synechococcus* species (Figure 20.33), who, along with their relative *Prochlorococcus*, are the major primary producers of the ocean and account for over 30% of the CO_2 fixed globally (Section 20.11).

The two primary mechanisms of bacterial mortality, grazing by protists and lysis by bacteriophages, contribute about equally to cell death but differ greatly in their impact on marine food webs. Grazing moves carbon up through the food chain when bacteria are consumed by protozoa, which are then consumed by zooplankton, which in turn sustain higher trophic levels up to fish and larger organisms. In contrast, the cytoplasm released as dissolved organic matter (DOM) by viral attack on *Prochlorococcus* (Figure 20.33) and other marine microbes—estimated to be as much as 3 gigatons of carbon per year—decreases the transfer of carbon to higher trophic

Figure 20.32 Viruses in seawater. A water sample collected on a 0.02- μm (20-nm) pore size filter is stained with SYBR Green and viewed by epifluorescence microscopy. The tiny green dots are viruses while the larger, brighter dots are prokaryotic cells about 0.5 μm in diameter. Viruses are typically 10 times more abundant than the total of prokaryotic cells in seawater. Inset transmission electron micrographs show various marine bacterial viruses (scale bars, 100 nm in all images).

levels. Although providing a significant amount of organic matter for other microbes, this released carbon amounts to about 25% of primary production that could otherwise be used by grazing populations.

Most described marine bacteriophages are head-and-tail bacteriophages containing double-stranded DNA genomes (Baltimore class I, Figure 11.2); by contrast, described RNA-containing phages and non-tailed double-stranded DNA viruses are relatively rare. However, electron microscopic observations of marine water samples have revealed that non-tailed viruses appear to dominate in the global ocean, even though this group is almost completely missing from marine virus isolates and sequence collections. This mystery was at least partially solved by the discovery of an entirely new lineage of non-tailed double-stranded DNA bacteriophage called the *Autolykiviridae* (the group is named for Autolykos of Greek

Figure 20.33 Cyanophage infection of *Synechococcus*. Phase contrast–electron cryotomography sections of cells of *Synechococcus* in various stages of infection with phage Syn5. (a) Early. (b) Intermediate. (c) Late. Arrows point to phage particles.

Figure 20.34 *Autolykiviridae*. Thin-section electron micrograph of lysed marine *Vibrio* cells containing virions of *Autolykiviridae*, a family of non-tailed dsDNA viruses. The viruses contain a lipid-bilayer membrane with an outer wall surrounding the virus core. A single virion is approximately 30 nm in diameter. Arrows point to individual virions.

mythology, a shape-changing thief notable for being difficult to catch). The virion of the virus has a more-or-less icosahedral morphology (Figure 20.34). The *Autolykiviridae* were recovered from plaque assays (Section 5.3 and Figure 5.10) using marine *Vibrio* cells as host. When genome sequences of isolated *Autolykiviridae* were used to screen marine metagenomic and genomic libraries for related viruses, sequences homologous to the gene encoding the capsid protein of the *Autolykiviridae* were identified in 13 bacterial and archaeal phyla, including two of the most abundant marine groups, the *Alphaproteobacteria* and the *Thaumarchaeota*.

The discovery of this previously unrecognized virus family of very broad host range (infecting both *Bacteria* and *Archaea*) has filled a major gap in our understanding of environmental virology. It is likely that this approach to discovery—combining classic methods of bacteriophage isolation in laboratory culture and comparative metagenomic sequence analysis—will continue to expand our knowledge of the marine virosphere. For example, recognition that bacteriophages infecting *Pelagibacter* species (Figure 20.30) are widespread in the marine environment was also dependent on first describing the bacteriophage infecting laboratory cultures of the host bacterium.

Marine Viral Diversity

Although laboratory characterization remains the definitive approach to virus description, additional understanding of viral diversity is being provided by *viral metagenomics*. Since viruses lack universal marker genes that can be used for targeted surveys (such as rRNA genes in cellular microbes), metagenomic approaches are used to conduct diversity surveys. Viral metagenomics combines virus particle purification and sequencing of DNA isolated from the virus particles. The viral metagenome is the sum total of all the virus genes

in a particular environment. When combined with next-generation sequencing technologies, this approach has shown that a large part of genetic diversity on Earth resides with bacteriophages.

Several viral metagenomic studies have been undertaken, and they invariably show that immense viral diversity exists on Earth. For example, approximately 75% of the gene sequences found in viral metagenomic studies show no similarity to any other genes known, either viral or cellular. By comparison, surveys of bacterial metagenomes typically reveal approximately 10% unknown genes. However, viral metagenomics alone is generally not sufficient to identify the host(s) infected by a specific virus. Methods in development to improve host assignment include matching of CRISPR spacers (anti-viral defenses of *Bacteria* and *Archaea*, Section 9.12) to environmental viral sequences and identifying patterns of co-occurrence between viral populations and putative host bacteria. Thus, most viruses still await discovery and most viral genes have unknown functions. This makes the study of the virosphere and viral diversity one of the most exciting areas of microbiology today. A rough estimate thus far of marine viral diversity indicates that at least 200,000 different kinds of viruses exist in the world's oceans, harboring an enormous number of novel genes.

Viruses as Agents of Genetic Transfer in the Marine Environment

As we have seen, lysogenic bacteriophages can integrate into the genomes of their bacterial hosts (Section 5.6), and when they do, they can confer new properties on the cell. Moreover, some lytic phages facilitate the transfer of bacterial genes from one cell to another through the process of transduction, a major means of horizontal gene transfer in which a virus carries host genes between cells, for example by picking up host DNA and becoming a nonlytic *transducing particle* (Section 9.7). As agents of transduction, bacteriophages are thought to have a major influence on bacterial evolution by conferring new metabolic or other beneficial properties on recipient cells that allow them to successfully colonize new habitats.

A good example of bacteriophage gene transfer in marine systems are the “cyanophages,” phages that can transfer certain photosynthesis genes among strains of *Synechococcus* and *Prochlorococcus*. When these phages are released from their lysed host cells (Figure 20.33), some of them incorporate host genes that encode photosystem (PS) II, one of the key components of oxygenic photosynthesis (Section 14.6). When such a phage infects a new host cell, it provides the cell with genes encoding a modified PSII. It is hypothesized that a more diverse complement of PSII proteins improves both cell and phage fitness by allowing the host cell to better adapt to changing environmental conditions—for example, changes in light intensity or light quality—and in the process, producing more cyanophage.

When host-derived genes were first found in temperate (nonlytic) bacteriophages, they were called lysogenic conversion factors. However, recognition that hostlike genes are widely distributed in both temperate and lytic viruses required the introduction of the much broader term **auxiliary metabolic genes (AMGs)**. During lytic infection, expression of AMGs alters host metabolism toward pathways that maximize production of new viral particles. For example, in the cyanobacteria–cyanophage system just described, the AMGs encode proteins that supplement photosynthetic electron transport

and redirect energy from carbon fixation to the pentose phosphate pathway (◀ Section 3.13) for increased production of ribose 5-phosphate, a nucleotide precursor needed to support virus replication. Similarly, cyanophages isolated from marine regions of low phosphate are more likely to have AMGs involved in phosphorus acquisition, such as genes for phosphate-binding protein (*pstS*) and alkaline phosphatase (*phoA*); this ensures that the host will have sufficient phosphate to produce cyanophage DNA.

Marine viruses infecting eukaryotes also encode AMGs. For example, an AMG of a virus infecting the calcareous phytoplankton *Emiliana huxleyi* (▶ Figure 21.20a and ▶ Section 18.7) alters host lipid biosynthesis pathways to produce lipids needed for viral particle assembly. Although viral metagenomics has shown that one way or the other, the most common AMGs affect nucleotide biosynthesis, viral AMGs can influence many different pathways of microbial metabolism, most often to the benefit of the virus and not the host.

Auxiliary Metabolic Genes in *Thaumarchaeota*

Archaea are abundant in the oceans, and a major group of marine *Archaea* of ecological importance is the *Thaumarchaeota* (▶ Section 17.5). These ammonia-oxidizing chemolithotrophs consume the vanishingly low levels of ammonia present in pelagic waters. Although lytic archaeal viruses have yet to be isolated for this group, several species of the archaeon *Nitrosopumilus* have been shown to harbor viral genomes within their chromosome (that is, the cells contain a provirus, ▶ Sections 5.6 and 5.7) whose genes suggest that the infecting virus was either of the head-and-tail dsDNA bacteriophage type (▶ Section 11.4) or icosahedral-shaped, similar to the herpesviruses (▶ Section 11.7). The discovery that these *Thaumarchaeota* proviruses contain an AMG homologous to the gene encoding a subunit of ammonia monooxygenase, the enzyme that catalyzes the first step in ammonia oxidation, was used to screen marine metagenomes for related viruses. From these results, 32 new thaumarchaeal viruses encompassing 15 putative viral species were identified in a variety of marine habitats. It is thus likely that at least some, and perhaps even many, of the viruses in seawater infect marine *Archaea* instead of marine *Bacteria* (Figure 20.31). This is bolstered by the observation that virtually all known archaeal viruses contain double-stranded DNA genomes (▶ Section 11.5 and Figures 11.3a and 11.13), and these are the most commonly observed viral genomes in the oceans.

Survival Strategies of Viruses in Nature

When hosts are plentiful in nature, it is thought that bacteriophages adopt the lytic lifestyle and thus large numbers of host cells are killed. By contrast, when host numbers are low, it may be difficult for viruses to find a new host cell, and under such circumstances, lysogeny would be favored if the virus is lysogenic (▶ Section 5.6). Under these conditions, the virus would survive as a prophage until host numbers increased and a lytic lifestyle could once again be supported. This hypothesis is consistent with the observation that in the depths of the ocean where bacterial numbers are lower than in surface waters, around half the bacteria examined have been found to contain one or more lysogenic viruses. As far as is known, no single-stranded DNA viruses and no RNA viruses can enter a lysogenic state, and so how these viruses might survive periods of low host numbers is unknown.

20.14 The Deep Sea

Light penetrates no farther than about 250 m in pelagic waters; as mentioned, this illuminated region is called the *photic zone* (Figure 20.29). Beneath the photic zone, down to a depth of about 1000 m, there is still considerable biological activity. However, water at depths greater than 1000 m is, by comparison, much less biologically active and is known as the *deep sea*. Greater than 75% of all

(a)

(b)

Figure 20.35 The deep-diving submersible *Limiting Factor*. (a) Deployment of the vessel. (b) Beginning a dive. This two-person vessel is capable of reaching depths of 11,000 meters with an operational dive time of 16 hours.

ocean water is deep-sea water, lying primarily at depths between 1000 and 6000 m. The deepest waters in the oceans lie below 10,000 m. However, because depressions this deep are very rare, the waters in them make up only a very small proportion of all pelagic waters.

The biology of the deepest ocean regions, the *abyssal zone* (below 4000 m) and the *hadal zone* (below 6000 m), has stirred the imagination for centuries. These regions remain among the least explored of Earth's biosphere because their study requires very specialized equipment. Only a few remotely operated vehicles (ROVs), autonomous underwater vehicles, and human-occupied submersibles can dive to the deepest marine waters, which exceed depths of 10,000 m; pressures at such depths are around 16,000 pounds per square inch (110,000 kilopascals). Among the newest generation of human-occupied submersibles is the *Limiting Factor* (Figure 20.35). This two-person vessel is capable of diving to 11,000 meters, allowing humans to directly visit and explore all regions of the ocean floor, including the very deepest—the Challenger Deep, which lies within the Mariana Trench (Pacific Ocean, depth of 10,900 m).

Conditions in the Deep Sea

Organisms that inhabit the deep sea face three major environmental extremes: (1) low temperature, (2) high pressure, and (3) low nutrient levels. In addition, deep-sea waters are completely dark such that photosynthesis relying on sunlight is impossible. Thus, microbes that inhabit the deep sea must be chemotrophic and able to grow under high pressure and oligotrophic conditions in the cold.

Below depths of about 1000 m, ocean water temperatures stay constant at 2–3°C. We discussed the responses of microorganisms to changes in temperature in Sections 4.11–4.13. As would be expected, many bacteria isolated from marine waters below 1000 m are psychrophilic (cold-loving) or at least psychrotolerant. However, since mesophilic microorganisms from warmer and more productive surface waters are constantly sinking through the water column, a variety of mesophiles can also be isolated from water collected at great depths. Deep-sea microbes must also be able to withstand the enormous hydrostatic pressures associated with great depths.

Figure 20.36 Growth of piezotolerant, piezophilic, and extremely piezophilic bacteria. Compare the slower growth rate of the extreme piezophile (right ordinate) with the growth rate of the piezotolerant and piezophilic bacteria (left ordinate) and note the inability of the extreme piezophile to grow at low pressures.

Figure 20.37 Pressure and temperature optima for cultured bacterial and archaeal piezophiles. Pressure is in pascals (Pa), the SI unit for pressure. One megapascal (MPa) corresponds to approximately 10 atmospheres. Note that different species of the same genus (for example, *Moritella*) can have vastly different pressure optima. Data assembled by Doug Bartlett.

Pressure increases by 1 atm for every 10 m of depth in a water column. Thus, an organism growing at a depth of 5000 m must be able to withstand pressures of 500 atm. We will see that microorganisms in general are remarkably tolerant of high hydrostatic pressures; many species can withstand pressures of 500 atm, and some species can withstand far more than this. Moreover, from studies of deep-sea microbial diversity performed thus far, some unusual microbes call this extreme environment home.

Piezotolerant and Piezophilic Bacteria and Archaea

Different physiological responses to pressure are observed in different deep-sea microorganisms. Some organisms simply tolerate high hydrostatic pressure, but do not grow optimally under such pressure; these organisms are **piezotolerant** (Figure 20.36). By contrast, others actually *grow best* under elevated hydrostatic pressure; these are called **piezophiles**. Organisms isolated from surface waters down to about 3000 m are typically piezotolerant. In piezotolerant organisms, higher metabolic rates are observed at 1 atm than at 300 atm, although growth rates at the two pressures may be similar (Figure 20.36). However, piezotolerant isolates typically do not grow at pressures greater than about 500 atm (Figure 20.36).

By contrast, cultures derived from samples taken at greater depths, 4000–6000 m, are typically piezophilic, growing optimally at pressures of around 300–400 atm. However, although piezophiles grow best under high pressure, they can still grow at 1 atm (Figure 20.36). In even deeper waters (for example, 10,000 m), **extreme piezophiles** (also called *hyperpiezophiles*) are present. These organisms require very high pressure for growth (Figure 20.37). For example, the extreme piezophile *Moritella* MT-5 isolated from the Mariana Trench

Figure 20.38 Sampling the deep sea. The unmanned Japanese submersible *Kaiko* collecting a sediment sample on the seafloor of the Mariana Trench off the Philippines at a depth of 10,897 m. The tubes of sediment are used for enrichment and isolation of piezophilic bacteria, such as the extreme piezophile (*Moritella*) isolated from this seafloor.

(Pacific Ocean, >10,000-m depth) (Figure 20.38) grows optimally at a pressure of 700–800 atm (Figure 20.37) and grows nearly as well at 1035 atm, the pressure it experiences in its natural habitat. The current pressure champion, *Colwellia marinimaniae*, was isolated from the Challenger Deep. This obligately hyperpiezophilic psychrophile is a member of the *Gammaproteobacteria* and grows at pressures between 80 and 140 MPa, with an optimum growth pressure of 120 MPa and optimum growth temperature of 6°C.

Molecular Effects of High Pressure

High pressure affects cellular physiology and biochemistry in many ways. In general, pressure decreases the ability of the subunits of multi-subunit proteins to interact. Thus, large protein complexes in extreme piezophiles must interact in such a way as to minimize pressure-related effects. Protein synthesis, DNA synthesis, and nutrient transport are sensitive to high pressure. Piezophilic bacteria grown under high pressure have a higher proportion of unsaturated fatty acids in their cytoplasmic membranes than when grown at 1 atm. Unsaturated fatty acids allow membranes to remain functional and

keep from gelling at high pressures or at low temperatures. The rather slow growth rates of extreme piezophiles compared with other marine bacteria (Figure 20.36) are likely due to the combined effects of pressure and low temperature; low temperature slows down the reaction rates of enzymes, directly affecting cell growth (◀ Section 4.11).

Studies of gene expression and adaptive features contributing to growth at high pressure require special pressurized incubation devices (Figure 20.39). These studies have shown that when a gram-negative piezophile is grown under high pressure, a specific outer membrane protein called OmpH (outer membrane protein H) is present that is absent from cells grown at 1 atm. OmpH is a type of porin. Porins are proteins that form channels through which molecules diffuse into the periplasm (◀ Section 2.4 and Figure 2.12c). Presumably, the porin made by cells grown at 1 atm cannot function properly at high pressure and thus a different porin must be synthesized. Interestingly, pressure controls transcription of *ompH*, the gene encoding OmpH. In characterized gram-negative piezophiles, a pressure-sensitive membrane protein complex is present that monitors pressure and triggers transcription of *ompH* only when conditions of high pressure warrant it. Transcriptomic analyses (◀ Section 10.8) indicate that even relatively modest changes in hydrostatic pressure alter the expression of a large number of genes in piezophiles, so it is likely that many other pressure-monitoring proteins exist in these organisms.

There remains much to explore in the abyssal and hadal zones of the ocean. As we discussed in Chapter 19, recent advances in metagenomics and high-throughput sequencing have revolutionized studies of deep-sea microbes and their adaptive strategies, such as alterations in membrane and protein structure that allow growth under such extreme conditions. Diversity studies have shown that both free-living and particle-attached archaeal and bacterial piezophiles are abundant, and that most have not yet been cultured. For example, *Bacteria* related to the phyla *Marinimicrobia* (Figure 20.31) and *Gemmatimonadetes* are enriched at these great depths. Since no member of the *Marinimicrobia* has been isolated and the few *Gemmatimonadetes* available are from soils or wastewater, a more complete understanding of the unique properties of these hadal *Bacteria* awaits their future cultivation. Ammonia-oxidizing *Archaea* related

Figure 20.39 Pressure cells for growing piezophiles under elevated pressure. (a) Photo of several pressure cells incubating in a cold room (4°C). (b) Schematic design of a pressure cell. These vessels are designed to maintain pressures of 1000 atm. Illustration based on drawing by Doug Bartlett.

to *Nitrosopumilus* (*Thaumarchaeota*, ◀ Section 17.5), an organism common in the upper marine water column, are also among the most abundant free-living *Archaea* in hadal waters, highlighting their global dominance in both marine and terrestrial environments. Thus, presence of these novel *Archaea* and *Bacteria* at great depths points to a unique hadal microbiology that we are only now beginning to more fully explore.

- How does pressure change with depth in a water column?
- What molecular adaptations are found in piezophiles that allow them to grow optimally under high pressure?

20.15 Deep-Sea Sediments

In addition to deep-sea waters, another vast and mostly unexplored microbial biosphere exists below the seafloor in the deep-sea sediments. Drilling expeditions to explore far below the ocean seafloor have revealed both archaeal and bacterial populations in sediment cores taken at depths greater than 2000 m (Figure 20.40). Most studies thus far have focused on relatively organic-rich sediments along continental margins. Here, cell numbers typically decrease from about 10^9 cells/g in surface sediment to about 10^6 cells/g at depths as great as 1000 m below the seafloor. In these coastal sediments, sulfate-reducing bacteria and other anaerobes deplete sulfate and other electron acceptors within a few meters of the sediment–water interface (Figure 20.22). This depletion of electron acceptors and organic matter with increasing depth constrains energy available to the deep subsurface microbial communities, accounting for the major decrease in cell numbers with depth (Figure 21.29).

Cell Numbers in Deep-Sea Sediments

The better-studied continental margins and shelf sediments are not representative of most of the ocean floor, about 90% of which is at greater than 2000-m depth and associated with marine waters of low productivity and therefore of much lower organic matter content (Figure 20.22). In the absence of significant transport of organic material to the sediment surface, sulfate and other electron acceptors may permeate all the way through the sediments to the underlying bedrock. However, because of the dearth of organic matter, cell numbers in these sediments are several orders of magnitude lower than in organic-rich sediments, ranging from about 10^6 cells/gram at the surface to fewer than 10^3 cells/gram at depths of a few hundred meters (Figure 20.41). Cell counts in all sediments generally decline significantly with depth, reflecting lower organic carbon availability and catabolic quality in older deep sediment material. Despite these low numbers, because deep-sea sediments are so vast, it has been estimated that a total of $\sim 5.4 \times 10^{29}$ prokaryotic cells exist in deep-sea sediments ($\sim 4 \times 10^{15}$ g), a number similar to the sum total in all the oceans.

Figure 20.41 also shows that cell numbers can deviate from the global regression as a function of spotty distributions of resources with depth at any particular drill site. In the example shown in Figure 20.41, cell numbers in coastal plain sediments are elevated near methane (cold) seeps (Figure 20.22), a region associated with active anaerobic methane oxidation (◀ Section 14.16), and in coal bed deposits (Figures 20.22 and 20.41), where, in addition to coal, associated organic materials boost electron donor availability. Other than these nutrient “oases,” nutrient limitation in deep sea sediments greatly restricts the size of indigenous microbial communities.

Figure 20.40 Drilling deep-sea sediments. (a) Deep-sea drilling vessel the JOIDES Resolution. Inset: Red dot indicates the location of sediment sampling in the Peru Basin. (b) Sediment cores recovered from the Peru Basin at 4800-m depth. Cores were split lengthwise to allow subsampling for molecular characterization. See Section 20.5 and Figure 20.10 for discussion of sulfide-oxidizing microbial mats that develop on the sediment surface off the Chilean and Peruvian coasts.

Figure 20.41 Microbial cell numbers in deep-sea sediments. Depth-related cell abundance from the analysis of one coastal sediment (filled circles) and the global average for all sampled ocean sediments (dashed regression line) based on cell count data.

A Phylogenetic Snapshot of Marine Sediment Prokaryotic Diversity

Marine sediment communities have been explored only to a limited extent because of the difficulty and expense of obtaining uncontaminated drilling cores from great depths (Figure 20.40). However, analyses of 16S ribosomal RNA gene sequences obtained by using PCR methods (◀ Section 19.6) on deep core samples have clearly established that novel *Archaea* make up a large fraction of the archaeal diversity and that bacterial diversity in both deep and shallow marine sediments is dominated by *Proteobacteria* (Figure 20.42). This abundance of *Proteobacteria* is also true of all the other habitats explored by culture-independent techniques (Figures 20.14, 20.20, 20.31, and see Figure 20.47).

Within marine sediment *Proteobacteria*, phylotypes associated with sulfate-reducing bacteria such as the *Desulfobacterales* are quite common (Figure 20.42), which is consistent with the fact that sulfate reduction (◀ Sections 14.12 and 15.11) is the major form of anaerobic respiration in marine sediments. *Bacteroidetes* and the unclassified/minor groups are also well represented in shallow marine sediments. Although abundant in marine waters, cyanobacteria compose just a tiny proportion of the total cell population in the permanently dark and anoxic sediments and probably represent cells that have reached the sediments after attaching to a particle or dead animal that eventually sank.

In addition to a variety of *Bacteria*, novel phyla of *Archaea* unrelated to cultured representatives are widespread in the deep subsurface. Genome sequences of uncultured *Bathyarchaeota* recovered

from both terrestrial and marine sediments (Figure 20.16) revealed a physiological capacity to degrade and assimilate protein and a capacity for some species to degrade carbohydrates. Other *Bathyarchaeota* appear to carry out methanogenesis and are autotrophs, likely existing on the small amounts of H_2 produced from geochemical reactions (Section 20.8) in deep sediments.

Energy Limitation and Microbial Life Below the Seafloor

How microbes in the deepest marine sediments survive in their nutrient-depleted environment remains unclear, but it is likely that they employ many of the strategies we have seen in marine pelagic microbes including small cell size (Figure 20.17) and small, compact genomes. Sequencing of 16S ribosomal RNA genes selectively amplified by PCR (◀ Section 19.6) using DNA extracted from deep drilling cores, as well as from more limited metagenomic surveys, has identified relatively few sequences related to the classical sulfate-reducing bacteria (◀ Section 15.11) or methanogenic and known methane-oxidizing *Archaea* (◀ Sections 14.16, 15.15, and 17.2), organisms that by contrast are quite common in surface sediments. Thus, from a nutritional standpoint, how do buried cells thrive under conditions of extreme electron donor limitation?

In the marine environment, easily degraded organic material is removed by microbial respiration in the water column and anaerobic respiration in surficial sediments (the sediments at and near the sediment surface), leaving behind a dilute pool of less readily degradable organic material that slowly trickles down into deeper sediments. Microbes that inhabit the deep sediments presumably utilize this low-quality organic material along with organic carbon released from dead cells as electron donors in energy metabolism. However, since representative organisms have yet to be isolated from deep sediments, our understanding of the supporting energy-conserving metabolisms is sketchy and can only be inferred from a few partial genome sequences assembled from metagenomes (◀ Sections 10.7 and 19.8) or obtained from single cells isolated directly from sediments, using single-cell genomic technology (◀ Section 10.11). Various known and yet-to-be-discovered forms of anaerobic respiration and fermentation are the most likely candidates for deep-sea sediment metabolisms, perhaps along with other metabolic options not obvious from the conditions known to exist in deep marine sediments. Also, with growth rates of deep sediment microbes likely to be near the slowest of any on Earth, tiny amounts of organic material may be all that these cell numbers need to survive in small populations for extended periods.

Since sediment microorganisms largely control the fate of carbon in this vast subsurface reservoir of organic matter, the discovery of novel *Archaea* (Figure 20.16) living at the thermodynamic edge of life has given microbial ecologists a new perspective on carbon cycling in marine sediments. However, the extent to which abiotic processes may also contribute energy sources to these buried microbes is unclear but could be significant. For example, the higher temperatures found at greater depths may promote the alteration of organic material, releasing methane and other hydrocarbons, H_2 , acetate, and CO_2 that may diffuse upwards to nourish microbes inhabiting the deep sediment biosphere. There is clearly much more to learn about the microbial ecology of Earth's deep subsurface, both in terrestrial and marine sediment contexts.

Figure 20.42 Marine sediment bacterial and archaeal diversity. The results are pooled analyses of 13,360 16S ribosomal RNA gene sequences from several studies of shallow and deep marine sediments. Many of the groups indicated are covered in Chapters 15 and 16 (*Bacteria*) or 17 (*Archaea*). For *Proteobacteria*, major subgroups are indicated. Note the high proportion of archaeal sequences and of *Gamma*-, *Delta*-, and *Epsilon*proteobacteria. Data assembled and analyzed by Nicolas Piel. Compare the prokaryotic diversity of marine sediments with that of open ocean water shown in Figure 20.31.

Check Your Understanding

- Give two reasons why sulfate-reducing bacteria are common in shallow marine sediments.
- How and why do the numbers of bacterial and archaeal cells vary with depth in marine deep sediments?
- What alternative sources of energy are suggested to nourish microorganisms in extremely deep marine sediments?

20.16 Hydrothermal Vents

Although we have thus far described the deep sea and deep-sea sediments as a remote, low-temperature, high-pressure, oligotrophic environment suitable only for slow-growing piezotolerant and piezophilic microorganisms (Section 20.14), there are some amazing exceptions. Thriving animal and microbial communities cluster in and around deep-sea hot springs throughout the world. These hot springs are located at depths from less than 1000 m to greater than 4000 m in regions of the seafloor where volcanic magma and hot rock have caused the floor to split open at crustal spreading centers (Figure 20.22 and Figure 20.43), or where iron and magnesium minerals associated with ancient rocks react with seawater and generate heat. Seawater seeping into these dynamic cracking regions of the crust reacts with hot rock, resulting in hot springs saturated with inorganic chemicals and dissolved gases. Collectively, these types of underwater hot springs are called **hydrothermal vents**. We discuss several remarkable symbiotic associations between hydrothermal vent-associated animals and microorganisms in Chapter 23. Here we consider the vent environment as a habitat for free-living microbes.

Figure 20.43 Hydrothermal vents. Schematic showing geological formations and major inorganic chemicals and minerals that are emitted from warm vents and black smokers. In warm vents, the hot hydrothermal fluid is cooled by cold 2–3°C seawater permeating the sediments. In black smokers, hot hydrothermal fluid near 350°C reaches the seafloor directly. The term “surficial” is a geological term meaning surface, in this case, the top layers of sediment.

Types of Vents

Volcanic hydrothermal systems are typically either warm (~ 5 to $>50^\circ\text{C}$), diffuse vents or very hot vents that emit hydrothermal fluids at 270 to $>400^\circ\text{C}$. The gently flowing, warm, diffuse fluids are emitted from cracks in the seafloor and the exterior walls of hydrothermal chimneys. The fluids originate from the mixing of cold seawater with hot hydrothermal fluids in subsurface regions of the sediments. Hot vents, called *black smokers*, form upright sulfide edifices called *chimneys* that can be less than 1 m to over 30 m in height. Chimneys form when acidic hydrothermal fluids rich in dissolved metals and magmatic gases are suddenly mixed with cold, oxygenated seawater. The rapid mixing causes fine-grained metal sulfide minerals such as pyrite and sphalerite to precipitate out, forming dark, buoyant plumes that rise above the seafloor (Figure 20.44).

A quite different type of hydrothermal vent environment is the “Lost City” formation located in the mid-Atlantic Ocean. Lost City is formed from the exposure of minerals associated with ocean crust 1 – 2 million years old that was once deep beneath the seafloor. Geological faults in these slow-spreading systems exposed magnesium and iron-rich rocks called *peridotites* at the seafloor. Chemical reactions of seawater and newly exposed peridotite are highly exothermic, generating heat and also driving the pH up to as high as pH 11. Extremely high levels of H_2 , CH_4 , and other low-molecular-weight hydrocarbons are also present in the hot (200°C) hydrothermal fluids. In contrast to the acidic volcanic black smoker systems (Figure 20.44), which are relatively transient, mixing of these alkaline fluids with seawater results in the formation of calcium carbonate (limestone) chimneys (Figure 20.45) that can reach up to 60 m in height and be active for $100,000$ years or more.

Robert D. Ballard

Figure 20.44 A hydrothermal vent black smoker emitting sulfide- and mineral-rich water at temperatures of 350°C . The walls of the black smoker chimneys display a steep temperature gradient and contain several types of *Bacteria* and *Archaea*.

Deborah Kelley, University of Washington

Figure 20.45 Massive carbonate chimney formation at Lost City peridotite-hosted vent system. Microbial colonization of freshly exposed mineral surfaces was studied by placing sterile mineral fragments in the green-topped device positioned over an actively venting area of the chimney. The diameter of the cylindrical collection device is approximately 10 cm. In contrast to the highly sulfidic vents (Figure 20.44), Lost City hydrothermal fluids are alkaline and lack sulfide but are rich in H_2 and CH_4 .

Bacteria and Archaea in Hydrothermal Vents

Chemolithotrophic metabolisms (◀ Table 14.1) dominate hydrothermal vent microbial ecosystems (Figure 20.22). Sulfidic vents support sulfur-oxidizing bacteria, whereas vents that emit other inorganic electron donors support nitrifying, hydrogen-oxidizing, iron- and manganese-oxidizing, or methylotrophic bacteria, the latter presumably growing on the CH_4 and carbon monoxide (CO) emitted from the vents. Table 20.2 summarizes the inorganic electron donors and electron acceptors that are thought to play a role in chemolithotrophic metabolisms at hydrothermal vents.

Although microbes cannot survive in the superheated hydrothermal fluids of black smokers, thermophilic and hyperthermophilic organisms do thrive in the gradients that form as the superheated water mixes with cold seawater. For example, within the walls of smoker chimneys can be found hyperthermophiles such as *Methanopyrus*, a species of *Archaea* that oxidizes H_2 and makes CH_4 (◀ Section 17.2). In fact, phylogenetic FISH staining (◀ Section 19.5) has detected cells of both *Bacteria* and *Archaea* in smoker chimney walls (Figure 20.46). The most thermophilic of all known sulfur-reducing microbes, species of *Pyrolobus* and *Pyrodictium* (Chapter 17), were isolated from black smoker chimney walls. In contrast to the significant microbial diversity in volcanic vent chimney walls, the carbonate chimney walls of the Lost City vents are primarily

Figure 20.46 Phylogenetic FISH staining of sulfidic black smoker chimney material. Taken from the Snake Pit vent field in the Mid-Atlantic Ridge, depth of 3500 m. A green fluorescing dye was conjugated to a probe that reacts with the 16S rRNA of all *Bacteria* and a red dye to a 16S rRNA probe for *Archaea*. The hydrothermal fluid going through the center of this chimney was at 300°C.

populated by methanogens of the genus *Methanosarcina* and are nourished by the H₂-rich fluids that permeate the porous, CO₂-rich chimney walls.

When smokers plug up from mineral debris, hyperthermophiles presumably drift away to colonize active smokers and somehow become integrated into the growing chimney wall. Surprisingly, although they require very high temperatures for growth, hyperthermophiles are quite tolerant of cold temperatures and oxygen. Thus, transport of cells from one vent site to another in cold oxic seawater apparently is not a problem.

Figure 20.47 Hydrothermal vent bacterial and archaeal diversity. The results are pooled analyses from several studies of the 16S rRNA gene content of warm and hot hydrothermal vents. Many of these groups are covered in Chapters 15 and 16 (*Bacteria*) or 17 (*Archaea*). For *Proteobacteria*, major subgroups are indicated. Note the high proportion of *Archaea* and of *Epsilonproteobacteria*. The physiology of many of these organisms is summarized in Table 20.2. Most of the chemolithotrophs listed in Table 20.2 grow with CO₂ as carbon source (autotrophic growth). Data assembled and analyzed by Nicolas Pinel.

TABLE 20.2 Chemolithotrophic <i>Bacteria</i> and <i>Archaea</i> present near deep-sea hydrothermal vents ^a			
Chemolithotroph	Electron donor	Electron acceptor	Product from donor
Sulfur-oxidizing	HS [−] , S ⁰ , S ₂ O ₃ ^{2−}	O ₂ , NO ₃ [−]	S ⁰ , SO ₄ ^{2−}
Nitrifying	NH ₄ ⁺ , NO ₂ [−]	O ₂	NO ₂ [−] , NO ₃ [−]
Sulfate-reducing	H ₂	S ⁰ , SO ₄ ^{2−}	H ₂ S
Methanogenic	H ₂	CO ₂	CH ₄
Hydrogen-oxidizing	H ₂	O ₂ , NO ₃ [−]	H ₂ O
Iron- and manganese-oxidizing	Fe ²⁺ , Mn ²⁺	O ₂	Fe ³⁺ , Mn ⁴⁺
Methylotrophic	CH ₄ , CO	O ₂	CO ₂

^aSee Chapter 14 for detailed discussions of these metabolisms and Chapters 15–17 for further coverage of each group of organisms.

A Phylogenetic Snapshot of Hydrothermal Vent Prokaryotic Diversity

Using a variety of molecular methods (◀ Section 19.6–19.8), studies of the prokaryotic diversity present near volcanic hydrothermal vents have revealed an enormous diversity of *Bacteria*. These 16S rRNA gene sequence surveys include waters near both warm and hot vents. Hydrothermal vent microbial communities are dominated by *Proteobacteria*, in particular *Epsilonproteobacteria* (◀ Section 16.5; Figure 20.47). *Alpha*-, *Delta*-, and *Gammaproteobacteria* are also abundant, whereas *Betaproteobacteria* are much less so.

Many *Epsilon*- and *Gammaproteobacteria* oxidize sulfide and sulfur as electron donors with either O_2 or nitrate (NO_3^-) as electron acceptors (Chapter 16). As shown in the detailed diagram of *Proteobacteria* in Figure 20.47, vent *Epsilonproteobacteria* phylotypes most closely match those of chemolithotrophic sulfur bacteria such as *Sulfurimonas*, *Arcobacter*, *Sulfurovum*, and *Sulfurospirillum*. These bacteria oxidize reduced sulfur compounds as electron donors (◀ Sections 14.7 and 15.12), and such a physiology is consistent with their presence near vent fluids charged with sulfur and sulfide. In addition, most *Deltaproteobacteria* specialize in anaerobic metabolisms using oxidized sulfur compounds as electron acceptors.

In contrast to *Bacteria*, the diversity of volcanic hydrothermal vent *Archaea* is more limited. Estimates of the number of unique phylotypes indicate that the diversity of *Bacteria* near hydrothermal vents is about 10 times that of *Archaea*. However, *Archaea* prevail in samples recovered from the walls of hot vent chimneys (Figure 20.46). Most of the *Archaea* detected near hydrothermal vents are either methanogens (◀ Section 17.2) or species of marine *Crenarchaeota* and *Euryarchaeota* (Chapter 17). With the exception of the ammonia-oxidizing *Nitrosopumilus* (*Thaumarchaeota*, ◀ Section 17.5), organisms in these groups remain uncultured and their physiologies poorly understood.

As we close this chapter dedicated to microbial ecosystems, it should be clear that any environment capable of supporting microbial life will be colonized with one or more microorganisms. The microbes present in each environment are typically a reflection of those whose metabolisms are most compatible with the conditions and resources available. But whether an ecosystem is nutrient robust or nearly devoid of nutrients, microbial communities will develop, and populations within a community will rise or fall in response to the dynamics of their environment.

Check Your Understanding

- How does a warm hydrothermal vent differ from a black smoker, both chemically and physically?
- Why is 350°C water emitted from a black smoker not boiling?
- Which phylum of *Bacteria* and which subgroups of this phylum dominate hydrothermal vent ecosystems, and why?

CHAPTER REVIEW

I • Microbial Ecology

- 20.1** Ecosystems consist of organisms, their environments, and all of the interactions among the organisms and environments. The organisms are members of populations and communities and are adapted to habitats. Species richness and abundance are aspects of species diversity in a community and an ecosystem.

Q Explain the difference between an ecosystem and a habitat. Why are some microbial habitats unsuitable for plant and animal life?

- 20.2** Microbial communities consist of guilds of metabolically similar organisms. Microorganisms play major roles in energy transformations and biogeochemical processes that result in the recycling of elements essential to living systems.

Q Describe two ways in which the diversity of microbial species in a community can be expressed.

II • The Microbial Environment

- 20.3** The niche for a microorganism consists of the specific assortment of biotic and abiotic factors within a microenvironment in which that microorganism can be competitive. Microorganisms in nature often live a feast-or-famine existence such that only the best-adapted species reach high population densities in a given niche. Cooperation

among microorganisms is also important in many microbial interrelationships.

Q Why are extended periods of exponential microbial growth in nature rare and often slower than rates recorded in laboratory settings?

- 20.4** When surfaces are available, bacteria grow in attached masses of cells called biofilms. Biofilm formation confers several protective advantages on cells. Biofilms can have significant medical and economic effects on humans when unwanted biofilms develop on inert as well as living surfaces.

Q What property of biofilm microbial communities makes them clinically and industrially relevant? Why do biofilms possess this property? How can this cause problems in many instances?

- 20.5** Microbial mats can be phototrophic or chemolithotrophic. Phototrophic cyanobacterial mats are thick biofilms consisting of microbial cells and trapped particulate materials and are widespread in hypersaline or thermal waters. Mats of iron-oxidizing microorganisms are common in low-pH and metals-rich waters of geothermal springs and mining waste waters. Sulfur-oxidizing chemolithotrophs form extensive mat communities on marine sediment surfaces below the photic zone at the oxygen–sulfide interface.

Q What is the importance of gliding motility in the formation of marine chemolithotrophic mat systems?

III • Terrestrial Environments

- 20.6** Soils are complex microbial habitats consisting of sand, silt, and clay and contain numerous microenvironments and niches. Microorganisms are present in the soil primarily attached to soil particles or plant roots. The most important factors influencing microbial activity in soil are the availability of water and nutrients. However, in very arid soils microorganisms play important roles in stabilizing soil structure.

Q In what soil horizon are microbial numbers and activities the highest, and why?

- 20.7** *Proteobacteria*, *Acidobacteria*, and *Bacteroidetes* are the most diverse groups of *Bacteria* in soil because their metabolisms fit best with the available resources. Among *Archaea*, only *Euryarchaeota* and *Thaumarchaeota* are commonly present in soils. Polluted soils contain different proportions of the same major groups of *Bacteria* but are also enriched in *Actinobacteria* and nearly devoid of *Thaumarchaeota*. Changes in soil microbial diversity due to pollution and climate change threaten global food supplies.

Q Based on their metabolism, why are *Thaumarchaeota* well suited to inhabit soils?

- 20.8** The deep subsurface is a significant microbial habitat that sustains chemolithotrophic populations whose resource demands are few and inorganic, such as CO_2 , SO_4^{2-} , N_2 , and H_2 . Novel phyla of small-celled *Archaea* are present in the deep subsurface of both terrestrial and marine sediment environments. The discovery of the Asgard superphylum has provided new understanding of the origin of eukaryotes.

Q Studies of the deep subsurface have identified populations of chemoorganotrophs. What types and sources of nutrients are available to those organisms?

IV • Aquatic Environments

- 20.9** In freshwater aquatic ecosystems, phototrophic microorganisms are the main primary producers. Most of the organic matter produced is consumed by bacteria, which can lead to depletion of oxygen in the environment. The BOD of a body of water indicates its relative content of organic matter that can be biologically oxidized.

Q How and in what way does an input of organic matter, such as sewage, affect the oxygen content of a river or stream?

- 20.10** Pelagic marine waters are more nutrient deficient than most freshwaters, yet substantial numbers of microbes inhabit the oceans. However, in some highly productive and expansive oceanic regions, oxygen can be drawn down to low or undetectable levels at depths between 100 and 1000 m; oxygen-depleted waters at these depths are called oxygen minimum zones (OMZs). Bacteria specialized in the biodegradation of petroleum are enriched in regions of natural seepage of petroleum and natural gas.

Q How is climate change related to the ongoing increase in size of OMZs?

- 20.11** The major oxygenic microbial phototrophs in the open oceans are the cyanobacterium *Prochlorococcus* and the alga *Ostreococcus*. Marine anoxygenic phototrophs include *Roseobacter* and its relatives, the aerobic phototrophic purple bacteria. Unlike other anoxygenic phototrophs, aerobic purple bacteria carry out photosynthesis only under aerobic conditions and thus are well suited to open ocean redox conditions.

Q How has single-cell genomics contributed to new understanding of factors controlling the diversity of *Prochlorococcus* in the ocean?

- 20.12** Species of *Bacteria* tend to predominate in marine surface waters, whereas in deeper waters *Archaea* and *Bacteria* make up similar shares of the microbial community. Most pelagic *Bacteria* are specialized to grow at very low nutrient concentrations, and many found in the photic zone use light to make ATP by rhodopsin-driven proton pumps. *Thaumarchaeota* and *Euryarchaeota* are the major *Archaea* inhabiting the oceans.

Q Many pelagic *Bacteria* can use light energy but are not considered “phototrophs” in the same sense as cyanobacteria or purple bacteria. Explain.

- 20.13** Marine viruses far outnumber total cell numbers in the ocean, greatly impact marine food webs, and confer new properties to their hosts as gene transfer agents. Phage-encoded auxiliary metabolic genes typically function to subvert host metabolism for increased virus production.

Q Describe two types of viral auxiliary metabolic genes and how they benefit the virus.

- 20.14** The deep sea is a cold, dark habitat where hydrostatic pressure is high and nutrient levels are low. Piezophiles grow best under pressure but do not require pressure, whereas extreme piezophiles require high pressure, typically several hundred atmospheres, for growth. Ammonia-oxidizing *Archaea* are among the most abundant free-living microbes in the deepest regions of the ocean.

Q What property is shared by piezotolerant, piezophilic, and extremely piezophilic microorganisms?

- 20.15** Deep-sea sediments show decreasing levels of nutrients with depth, and thus the microbes that reside there experience constant near-starvation conditions. Although not yet cultured, novel phyla of *Archaea* inhabit deep marine sediments (as well as the terrestrial deep subsurface), and these organisms likely survive by scavenging the trace levels of both organic matter and electron acceptors present there.

Q What sources of organic matter in deep-sea sediments could be used to support growth?

- 20.16** Hydrothermal vents are deep-sea hot springs where either volcanic activity or unusual chemistry generates fluids containing large amounts of inorganic electron donors (such as sulfide, ammonia, and hydrogen) that can be used by various chemolithotrophic bacteria.

Q Would you expect to find the same types of microorganisms associated with black smoker and carbonate vent systems? Explain.

APPLICATION QUESTIONS

1. Imagine a sewage plant that is releasing sewage containing high levels of ammonia and phosphate and very low levels of organic carbon. Which types of microbial blooms might be triggered by this sewage? How would the graphs of oxygen near and beyond the plant's release point differ from the graph shown in Figure 20.19a?
2. Keeping in mind that the open-ocean waters are highly oxic, predict the possible metabolic lifestyles of open-ocean *Archaea* and *Bacteria*. How might rhodopsin-like pigments be more abundant in one group of organisms than in the other?
3. Warming associated with climate change has been suggested to result in reduced transfer of oxygen to deeper waters in the ocean. How might such warming also result in reduced nutrient availability to planktonic species in marine surface waters?

CHAPTER GLOSSARY

Auxiliary metabolic genes (AMGs) virus-encoded genes that alter host metabolism toward pathways that maximize production of new virus particles

Biochemical oxygen demand (BOD) the relative amount of dissolved oxygen consumed by microorganisms for complete oxidation of bioavailable organic and inorganic material in a water sample

Biofilm colonies of microbial cells encased in a porous organic matrix and attached to a surface

Biogeochemistry the study of biologically mediated chemical transformations in the environment

Community two or more cell populations coexisting in a certain area at a given time

Ecosystem a dynamic complex of organisms and their physical environment interacting as a functional unit

Epilimnion the warmer and less dense surface waters of a stratified lake

Extreme piezophile an organism requiring several hundred atmospheres of pressure for growth

Guild metabolically similar microbial populations that exploit the same resources in a similar way

Habitat a part of the ecosystem best suited to one or a few populations

Hydrothermal vent a deep-sea hot spring emitting warm ($\sim 20^{\circ}\text{C}$) to superheated ($>300^{\circ}\text{C}$) water

Hypolimnion the colder, denser, and often anoxic bottom waters of a stratified lake

Microbial mat a thick, layered, diverse community nourished either by light in a hypersaline or an extremely hot aquatic environment, in which cyanobacteria are essential; or by chemolithotrophs growing on the surface of sulfide-rich marine sediments

Microenvironment a micrometer-scale space surrounding a microbial cell or group of cells

Niche in ecological theory, the biotic and abiotic characteristics of the microenvironment that contribute to an organism's competitive success

Oligotroph an organism that grows only or grows best at very low levels of nutrients

Oxygen minimum zone (OMZ) an oxygen-depleted region of intermediate depth in the marine water column

Piezophile an organism that grows best under a hydrostatic pressure greater than 1 atm

Piezotolerant able to grow under elevated hydrostatic pressures but growing best at 1 atm

Population a group of organisms of the same species in the same place at the same time

Primary producer an organism that synthesizes new organic material from CO_2 and obtains energy from light or from oxidation of inorganic compounds

Prochlorophyte a bacterial oxygenic phototroph that contains chlorophylls *a* and *b* but lacks phycobiliproteins

Proteorhodopsin a light-sensitive protein present in some pelagic *Bacteria* that fuels a proton pump that yields ATP

Rhizosphere the region immediately adjacent to plant roots

Species abundance the proportion of each species in a community

Species richness the total number of different species present in a community

Stratified water column a body of water separated into layers having distinct physical and chemical characteristics

Nutrient Cycles 21

MICROBIOLOGYNOW

An Uncertain Future for Coral Reef Ecosystems

Carbon dioxide (CO_2) released from the burning of fossil fuels is contributing to global warming and ocean acidification. Although all ecosystems will ultimately be impacted by this, coral reef ecosystems are particularly sensitive. About a quarter of the oceans' coral reefs have already been lost to thermal stress and pollution, and ongoing acidification is impairing their formation of calcium carbonate skeletons. Although occupying less than 1% of the ocean floor, coral reefs support about one-quarter of all marine species that provide food for millions of people. Thus it is essential that we quantify current rates of coral reef loss and predict potential future losses.

In an experimental study of adding CO_2 to ocean waters bathing a natural coral reef ecosystem, it was clear that even a minor reduction in pH greatly reduces the rate of biogenic calcification. This study, performed at a section of the Great Barrier Reef (Australia), used tidal flow from an upper to a lower lagoon to adjust the pH of water bathing the lower section of reef. A 4000-gallon floating tank of seawater was

first acidified by bubbling with CO_2 and then pumped from the edge of the upper lagoon during tidal change, reducing the pH in the lower lagoon from ambient pH (8.13) to a treatment level (7.98). A nonreactive red dye was added before release to follow the dilution of the acidified plume as it mixed with seawater (photo).

In this experiment, calcification rates were quantified by measuring changes in alkalinity (due to carbonate production) over a one-hour period in the pH-adjusted water compared with seawater maintained at the original pH. Remarkably, net calcification of this natural reef community was reduced 34% by this relatively small change in pH, showing that these remarkable and very sensitive ecosystems are in jeopardy unless a rapid reduction in global CO_2 emissions is initiated.

- II Other Nutrient Cycles 738
- III Humans and Nutrient Cycling 746

I • Carbon, Nitrogen, and Sulfur Cycles

The microbial cycling of carbon, nitrogen, and sulfur compounds provides essential nutrients for autotrophs. The organic matter these organisms produce is oxidized by heterotrophs and by human activities to CO₂, an excess of which contributes to the ongoing problem of global warming.

The key nutrients for life are cycled by both microorganisms and macroorganisms, but for each nutrient it is microbial activities that dominate. Understanding how microbial nutrient cycles work is important because the cycles and their many feedback loops are essential for plant agriculture and the overall health of a sustainable planet.

We begin our coverage of nutrient cycles with the carbon cycle. Major areas of interest here are the magnitude of carbon reservoirs on Earth, the rates of carbon cycling within and between reservoirs, and the coupling of the carbon cycle to other nutrient cycles. We emphasize the gases *carbon dioxide* (CO₂) and *methane* (CH₄) because they are major components of the carbon cycle and have major impacts on the global ecosystem. We return to the carbon cycle in Part III of this chapter to consider how human activities are affecting this critical nutrient cycle.

21.1 The Carbon Cycle

On a global basis, carbon (C) travels as CO₂ through all of Earth's major carbon reservoirs: the atmosphere, the land, the oceans, freshwaters, sediments and rocks, and biomass (Figure 21.1). As we have already seen for freshwater environments, the carbon and oxygen cycles are intimately linked (◀ Section 20.9). All nutrient cycles link in some way to the carbon cycle, but the nitrogen (N) cycle links particularly strongly because, other than water (H₂O), C and N make up the bulk of living organisms (◀ Section 4.1 and see Figure 21.6).

Mastering Microbiology
Art Activity:
Figure 21.1
The carbon cycle

5 UNIT

Carbon Reservoirs

By far the largest C reservoir on Earth is the sediments and rocks of Earth's crust (Figure 21.1), but the rate at which sediments and rocks decompose and carbon is removed as CO₂ is so slow that flux out of this reservoir is insignificant on a human time scale. A large amount of C is found in land plants. This is the organic C of forests, grasslands, and agricultural crops—the major sites of phototrophic CO₂ fixation. However, more C is present in dead organic material, called **humus**, than in living organisms. Humus is a complex mixture of organic materials that have resisted rapid decomposition and is derived primarily from dead plants and microorganisms. Some humic substances are quite recalcitrant, with a decomposition time of several decades, but certain other humic components decompose much more rapidly.

The most rapid means of transfer of C is via the atmosphere. Carbon dioxide is removed from the atmosphere primarily by photosynthesis of land plants and marine microorganisms and is returned to the atmosphere by respiration of animals and chemoorganotrophic microbes (Figure 21.1). The single most important contribution of CO₂ to the atmosphere is by microbial decomposition of dead organic material. However, since the Industrial Revolution, human activities have increased atmospheric CO₂ levels by nearly 40%, primarily from the combustion of fossil fuels. This rise in CO₂, a major *greenhouse gas*, has triggered global changes in climate, the most notable feature of which is steadily increasing global temperatures, a condition called **global warming** (see Section 21.9 and Figure 21.24). That global warming will affect microbial nutrient cycling is a virtual certainty because everything we know about the physiology of microorganisms tells us that microbial activities change in response to temperature. Whether these changes will be favorable or unfavorable to higher organisms (including humans) is a major area of active research today (Section 21.9).

Figure 21.1 The carbon cycle. The carbon and oxygen cycles are closely connected, as oxygenic photosynthesis both removes CO₂ and produces O₂, and respiration both produces CO₂ and removes O₂. The accompanying table shows that the greatest reservoir of carbon on Earth is in rocks and sediments, and most of this is in inorganic form as carbonates.

Figure 21.2 Redox cycle for carbon. The diagram contrasts autotrophic processes ($\text{CO}_2 \rightarrow$ organic compounds) and heterotrophic processes (organic compounds $\rightarrow \text{CO}_2$).

Photosynthesis and Decomposition

New organic compounds are biologically synthesized on Earth only by CO_2 fixation by autotrophs—the phototrophs and chemolithotrophs. Most organic compounds originate in photosynthesis and thus phototrophic organisms are the foundation of the carbon cycle (Figure 21.1). However, phototrophic organisms are abundant in nature only in habitats where light is available. The deep sea, deep terrestrial subsurface, and other permanently dark habitats are devoid of indigenous phototrophs. There are two groups of oxygenic phototrophic organisms: *plants* and *microorganisms*. Plants are the dominant phototrophic organisms of terrestrial environments, whereas phototrophic microorganisms dominate in aquatic environments.

The redox cycle for C (Figure 21.2) begins with photosynthetic CO_2 fixation, driven by the energy of light (◀ Sections 3.11, 3.12, 14.5, and 14.6):

CH_2O represents organic matter at the oxidation–reduction level of cell material. Phototrophic organisms also carry out respiration, both in the light and the dark. The overall equation for respiration is the reverse of oxygenic photosynthesis:

For organic matter to accumulate, the rate of photosynthesis must exceed the rate of respiration. In this way, autotrophic organisms build biomass from CO_2 , and then this biomass in one way or

another supplies the C heterotrophic organisms need. Anoxygenic phototrophs and chemolithotrophs also produce excess organic compounds, but in most environments the contributions of these organisms to the net accumulation of organic matter are minor compared to the inputs of oxygenic phototrophs. This is because the reductant used by oxygenic phototrophs, H_2O (◀ Section 14.3), is in virtually unlimited supply.

Organic compounds are degraded biologically to CH_4 and CO_2 (Figure 21.2). Carbon dioxide, most of which is of microbial origin, is produced by aerobic and anaerobic respirations (◀ Sections 3.8 and 3.9). Methane is produced in anoxic environments by *methanogens* from the reduction of CO_2 with hydrogen (H_2) or from the splitting of acetate into CH_4 and CO_2 (◀ Section 14.15). However, any naturally occurring organic compound can eventually be converted to CH_4 from the cooperative activities of methanogens and various fermentative bacteria, as we will see in Section 21.2. Methane produced in anoxic habitats is insoluble and most often diffuses rapidly to oxic environments where it is either released to the atmosphere or oxidized to CO_2 by *methanotrophs* (◀ Sections 14.16 and 15.15; Figure 21.2). Hence, most of the C in organic compounds eventually returns to CO_2 , and the links in the carbon cycle are closed.

Methane Hydrates

Although present in the atmosphere at lower levels than CO_2 , CH_4 is a potent greenhouse gas that is over 20 times more effective in trapping heat than is CO_2 . Some CH_4 enters the atmosphere from trapping heat than is CO_2 . Some CH_4 enters the atmosphere from methanogenic production, but not all biologically produced CH_4 is immediately consumed or released to the atmosphere. Huge amounts of CH_4 derived primarily from past microbial activities are trapped underground or under marine sediments as *methane hydrates* (Figure 21.1 and Figure 21.3), molecules of frozen CH_4 . Methane hydrates form when sufficient CH_4 is present in environments of high pressure and low temperature, such as beneath the permafrost in the Arctic and in marine sediments (Figure 21.1). These deposits can be up to several hundred meters thick and are estimated to

Figure 21.3 Burning methane hydrate. Frozen methane ice retrieved from marine sediments is ignited.

contain 700–10,000 petagrams ($1 \text{ petagram} \times 10^{15} \text{ g}$) of CH_4 . This exceeds other known CH_4 reserves on Earth by several orders of magnitude.

Methane hydrates are highly dynamic, absorbing and releasing CH_4 in response to changes in pressure, temperature (Figure 21.4), and fluid movement. Methane hydrates also fuel deep-water ecosystems, called either *cold seeps* or *methane seeps* (◀ Figure 20.24). Here, the slow release of CH_4 from seafloor hydrates nourishes not only anaerobic methane-oxidizing *Archaea* (◀ Section 14.16), but also animal communities that contain aerobic methane-oxidizing endosymbionts that oxidize CH_4 and release organic matter to the animals (▶ Section 23.11). Anaerobic oxidation of CH_4 is coupled to the reduction of sulfate (SO_4^{2-}), nitrate (NO_3^-), and iron and manganese oxides, reducing the amount of free methane released. Hydrogen sulfide (H_2S), produced by the oxidation of methane coupled to sulfate reduction (◀ Section 14.16), can nourish dense microbial mats of aerobic filamentous sulfur-oxidizing bacteria (◀ Section 14.7) on the seafloor overlaying methane hydrates (Figure 21.5; see also Section 20.5 and Figure 20.10).

Although deep oceanic methane hydrates are stabilized by high pressure, hydrates in shallower coastal sediments are much more sensitive to small changes in temperature (Figure 21.4). Hydrates in shallow sediments are at the margin of what is called the *gas hydrate stability zone* (GHSZ). In these marginal regions, relatively small changes in temperature can destabilize the hydrates. For example, on-site monitoring of hydrate deposits in a marine coastal plain showed them to be sensitive to $1\text{--}2^\circ\text{C}$ seasonal changes in bottom-water temperature. During periods of seasonally elevated water temperature, methane bubbles freely (a phenomenon called methane flares) from the sediments (Figure 21.4). In addition to the release of methane from marine and terrestrial hydrates, as permafrost melts, its huge reserve of organic matter could be catabolized by microbes, leading eventually to the production of yet more methane (Section 21.9).

Carbon Balances and Coupled Cycles

Although it is convenient to consider carbon cycling as a series of reactions separate from those in other nutrient cycles, in reality, all nutrient cycles are *coupled cycles*; major changes in one cycle affect the functioning of others. But certain cycles, such as the carbon and nitrogen cycles (Figure 21.6), are extremely closely coupled because of the large amount of C and N in living organisms. The rate of primary productivity (CO_2 fixation) is controlled by several factors, in

Figure 21.4 Seasonal flares of methane bubbling from methane hydrates. Methane hydrates in shallow coastal sediments are sensitive to seasonal changes in bottom water temperature. Flares of methane bubbles are observed when water temperatures warm by as little as $1\text{--}2^\circ\text{C}$.

David L. Valentine

Figure 21.5 Sulfur-oxidizing microbial mats overlying a deep-sea methane seep. This seep is located at 800 m depth in the Pacific Ocean, off Los Angeles, California. The oxidation of methane coupled to sulfate reduction in the subsurface produces abundant H_2S , which feeds a sediment surface community of filamentous sulfide-oxidizing bacteria. The bacteria are filled with inclusions of elemental sulfur (S^0), leading to the whitish color. The dark area near the bottom center is about 0.5 m long.

particular by the magnitude of photosynthetic biomass and by available N, often a limiting nutrient. Thus, large-scale reductions in biomass, for instance by widespread deforestation, reduce rates of primary productivity and increase levels of CO_2 . High levels of organic C stimulate microbial nitrogen fixation ($\text{N}_2 \rightarrow \text{NH}_3$, ◀ Section 3.12), and this in turn adds more fixed N to the pool for primary producers; low levels of organic C have just the opposite effect (Figure 21.6). High levels of ammonia (NH_3) stimulate primary production and nitrification (◀ Section 14.9), but inhibit nitrogen fixation. High levels of nitrate (NO_3^-), an excellent N source for plants and aquatic phototrophs, stimulate primary production but also increase the rate of denitrification (◀ Section 14.11); the latter removes fixed forms of N from the environment and feeds back in a negative way on primary production (Figure 21.6).

This simple example illustrates how nutrient cycles are anything but isolated entities. Instead, they are coupled systems that must maintain a delicate balance of inputs and outputs. Thus, one could expect the C and N cycles to respond to large inputs in specific components (for example, through inputs of CO_2 or nitrogen fertilizers) in ways that are not always beneficial to the biosphere and that can have unintended consequences for all life, including humans (Section 21.9).

Check Your Understanding

- How is new organic matter made in nature?
- In what ways are oxygenic photosynthesis and respiration related?
- Why is microbially produced methane typically formed only in anoxic environments?

Figure 21.6 Coupled cycles. All nutrient cycles are interconnected, but the carbon and nitrogen cycles are intimately coupled. In the carbon cycle, CO₂ supplies the C for carbon compounds. The N cycle, shown in more detail in Figure 21.9, supplies N for many biological compounds.

21.2 Syntrophy and Methanogenesis

Most organic compounds are oxidized in nature by *aerobic* microbial processes. However, because oxygen (O₂) is a poorly soluble gas and is actively consumed when available, much organic carbon still ends up in anoxic environments. Methanogenesis, the biological production of CH₄, is a major process in anoxic habitats and is catalyzed by a large group of *Archaea*, the *methanogens*, which are strict anaerobes. We discussed the biochemistry of methanogenesis in Section 14.15 and other aspects of methanogens in Section 17.2.

Most methanogens can use CO₂ as a terminal electron acceptor in anaerobic respiration, reducing it to CH₄ with H₂ as electron donor. Only a very few other substrates, chiefly acetate, are directly converted to CH₄ by methanogens (Section 14.15). To convert most organic compounds to CH₄, methanogens must team up with partner organisms called *syntrophs* that function to supply them with precursors for methanogenesis.

Anoxic Decomposition and Syntrophy

In Section 14.22 we discussed the biochemistry of **syntrophy**, a process in which two or more organisms cooperate in the anaerobic degradation of organic compounds. Here we consider the interactions of syntrophic bacteria with their partner organisms and their significance for the carbon cycle. Our focus will be anoxic freshwater sediments and anoxic wastewater treatment, both of which are major sources of CH₄.

Polysaccharides, proteins, lipids, and nucleic acids from dead organisms find their way into anoxic habitats, where they are catabolized. The monomers released by hydrolysis of these polymers become major electron donors for energy metabolism. For the breakdown of a typical polysaccharide such as cellulose, the process begins with *cellulolytic* bacteria (Figure 21.7). These organisms hydrolyze cellulose into glucose, which is catabolized by fermentative organisms to short-chain fatty acids (acetate, propionate, and butyrate), alcohols such as ethanol and butanol,

and the gases H₂ and CO₂. Hydrogen (H₂) and acetate are consumed by methanogens directly, but the bulk of the carbon remains in the form of fatty acids and alcohols; these cannot be directly catabolized by methanogens and require the activities of syntrophic bacteria (Section 14.22; Figure 21.7).

Syntrophic bacteria are called *secondary fermenters* because they ferment the products of the primary fermenters, yielding H₂, CO₂, and acetate as products. For example, *Syntrophomonas wolfei* oxidizes C₄ to C₈ fatty acids, yielding acetate, CO₂ (if the fatty acid was C₅ or C₇), and H₂ (Table 21.1 and Figure 21.7). Other species of *Syntrophomonas* use fatty acids up to C₁₈ in length, including some unsaturated fatty acids. *Syntrophobacter wolnii* specializes in propionate (C₃) fermentation, generating acetate, CO₂, and H₂, and *Syntrophus gentianae* degrades aromatic compounds such as benzoate to acetate, H₂, and CO₂ (Table 21.1).

Despite rather extensive metabolic diversity, syntrophs are unable to carry out any of these reactions in pure culture. Instead, they depend on a H₂-consuming partner organism because of the

Figure 21.7 Anoxic decomposition. In anoxic decomposition, various groups of fermentative anaerobes cooperate in the conversion of complex organic materials to CH₄ and CO₂. This pattern holds for environments in which sulfate-reducing bacteria play only a minor role; for example, in freshwater lake sediments, sewage sludge, bioreactors, and the rumen.

TABLE 21.1 Major reactions in the anoxic conversion of organic compounds to methane ^a			
Reaction type	Reaction	Free energy change (kJ/reaction)	
		$\Delta G^{0,b}$	ΔG^c
Fermentation of glucose to acetate, H ₂ , and CO ₂ ^d	Glucose + 4 H ₂ O → 2 acetate [−] + 2 HCO ₃ [−] + 4 H ⁺ + 4 H ₂	−207	−319
Fermentation of glucose to butyrate, CO ₂ , and H ₂	Glucose + 2 H ₂ O → butyrate [−] + 2 HCO ₃ [−] + 2 H ₂ + 3 H ⁺	−135	−284
Fermentation of butyrate to acetate and H ₂	Butyrate [−] + 2 H ₂ O → 2 acetate [−] + H ⁺ + 2 H ₂	+48.2	−17.6

^dCarbonic acid is formed by hydration of CO₂ dissolved in water. Since the deprotonated form of this acid is the major species at near neutral pH, HCO₃[−] is commonly used in many microbial reactions involving CO₂ as a reactant or product.

unusual bioenergetics linked to the syntrophic process. As described in Section 14.22, H₂ consumption by a partner organism is absolutely essential for growth of syntrophic bacteria (in the absence of other electron acceptors), and the association of H₂ producer and H₂ consumer can be very intimate. In fact, H₂ transfer in some syntrophic associations may not be directly via H₂ transfer but through *direct conduction*, where electrons are transferred between species using electrically conductive wire-like structures (Section 21.5; ◀ Section 14.13 and Figure 14.31). But no matter the mechanisms, it is the transfer of H₂ (or electrons) that makes the syntrophic association work. How is this so?

When the reactions listed in Table 21.1 for the fermentation of butyrate, propionate, ethanol, or benzoate are written with all reactants at standard conditions (solutes, 1 M; gases, 1 atm; 25°C), the reactions yield free-energy changes (ΔG^0 , ◀ Section 3.3) that are positive in arithmetic sign; that is, the reactions *require* rather than *release* energy. But the consumption of H₂ dramatically affects the energetics, making the reaction favorable and allowing energy to be conserved. This can be seen in Table 21.1, where the ΔG values (free-energy change measured under *actual conditions* in the habitat) are negative in arithmetic sign if H₂ concentrations are kept near zero by a H₂-consuming partner organism. This allows the syntrophic bacterium to conserve a small amount of energy that is used to produce ATP.

The final products of the syntrophic partnership are CO₂ and CH₄ (Figure 21.7), and any naturally occurring organic compound that enters a methanogenic habitat will eventually be converted to these products. This includes even complex aromatic and aliphatic hydrocarbons. Additional organisms other than those shown in Figure 21.7 may participate in such degradations, but eventually fatty acids and alcohols will be generated, and they will be converted into methanogenic substrates by syntrophs. Acetate produced by syntrophs (as well as by the activities of acetogenic bacteria, Figure 21.7 and ◀ Section 14.14) is a direct methanogenic substrate and is converted to CO₂ and CH₄ by various methanogens.

Methanogenic Symbionts and Acetogens in Termites

A variety of anaerobic protists that thrive under strictly anoxic conditions, including ciliates and flagellates (◀ Section 18.4), play a major role in the carbon cycle. Methanogenic *Archaea* live within some of these protist cells as H₂-consuming endosymbionts. For example, methanogens are present *within* cells of trichomonal protists inhabiting the termite hindgut (Figure 21.8) where methanogenesis and acetogenesis are major metabolic processes. Methanogenic symbionts of protists are species of the genera *Methanobacterium* or *Methanobrevibacter* (◀ Section 17.2 and Figure 17.5).

In the termite hindgut, endosymbiotic methanogens along with acetogenic bacteria are thought to benefit their protist hosts by consuming H₂ generated from glucose fermentation by cellulolytic protists. The acetogens are not endosymbionts but instead reside in the termite hindgut itself, consuming H₂ from primary fermenters and reducing CO₂ to make acetate. Unlike methanogens, acetogens can ferment glucose directly to acetate. Acetogens can also ferment methoxylated aromatic compounds to acetate. This is especially important in the termite hindgut because termites live on wood, which contains lignin, a complex polymer of methoxylated aromatic compounds (Figure 21.8b). The acetate produced by acetogens in the termite hindgut is consumed by the insect as its primary carbon and energy source. Microbial symbioses in the termite hindgut are discussed in more detail in Section 23.9.

Check Your Understanding

- Why does *Syntrophomonas* need a partner organism in order to ferment fatty acids or alcohols?
- To what extent does biogas formation depend on syntrophy?
- What substrates are used by acetogens to produce acetate?

Figure 21.8 Termites and their carbon metabolism. (a) A subterranean termite worker larva shown to the right of a hindgut dissected from another worker. The animal is about 0.5 cm long. (b) Partial structure of lignin, a component of wood. The methoxy groups (highlighted in blue) are substrates for acetogenesis. Two views of the same microscopic field show termite hindgut protists photographed by (c) phase-contrast and (d) epifluorescence. Endosymbiotic methanogens in the protist cells fluoresce blue-green because of the methanogenic coenzyme F_{420} (compare with ◀ Figure 14.37). The average diameter of the protist cells is 15–20 μm .

21.3 The Nitrogen Cycle

Nitrogen is an essential element for life (◀ Section 3.1) and exists in a number of oxidation states that are cycled by specific redox reactions. We have discussed four major microbial N transformations thus far: nitrification, denitrification, anammox, and nitrogen fixation (Chapter 14). These and other key N transformations are summarized in the redox cycle shown in Figure 21.9.

Nitrogen Fixation and Denitrification

Nitrogen gas (N_2) is the most stable form of N and is a major reservoir for N on Earth. However, only a relatively small number of *Bacteria* and *Archaea* are able to use N_2 as a cellular N source by the process of

nitrogen fixation ($\text{N}_2 + 8 \text{H} \rightarrow 2 \text{NH}_3 + \text{H}_2$) (◀ Section 3.12). The N recycled on Earth is mostly already “fixed N”; that is, N in combination with other elements, such as in ammonia (NH_3) or nitrate (NO_3^-). In many environments, however, the short supply of fixed N puts a premium on biological nitrogen fixation, and in these habitats, nitrogen-fixing bacteria flourish.

We discussed the role of NO_3^- as an alternative electron acceptor in anaerobic respiration in Section 14.11. Under most conditions, the end product of NO_3^- reduction is N_2 , nitric oxide (NO), or nitrous oxide (N_2O). The reduction of NO_3^- to these gaseous N compounds, called **denitrification** (Figure 21.9), is the main means by which N_2 and N_2O are formed biologically. Denitrification can be either beneficial or harmful. On the one hand, denitrification is a detrimental process. For example, if agricultural fields fertilized with NO_3^- fertilizer become waterlogged following heavy rains, anoxic conditions can develop and denitrification can be extensive; this removes fixed N from the soil. On the other hand, denitrification can aid in wastewater treatment (▶ Section 22.7). By converting NO_3^- in wastewater to volatile forms of N, denitrification minimizes the load of fixed N in discharge waters that triggers algal growth and loss of water quality (◀ Figure 20.19).

The production of N_2O and NO by denitrification can have other environmental consequences. Nitrous oxide can be photochemically oxidized to NO in the atmosphere. Nitric oxide reacts with ozone (O_3) in the upper atmosphere to form nitrogen dioxide (NO_2), which is further oxidized to form nitric acid (HNO_3) that returns to Earth as acid rain. In addition, N_2O is a very potent greenhouse gas. Although N_2O molecules persist on average only about 100 years because of their reactivity, on a per weight basis, the contribution of N_2O to global warming is about 300 times that of CO_2 . Thus, denitrification contributes to global warming; to O_3 destruction, which increases passage of ultraviolet radiation to the surface of Earth; and to acid rain, which increases acidity of soils. Increases in soil acidity change microbial community structure and function and, ultimately, soil fertility, impacting both plant diversity and agricultural yields of crop plants.

Ammonification and Ammonia Fluxes

Ammonia is released during the decomposition of organic N compounds such as amino acids and nucleotides, a process called *ammonification* (Figure 21.9). Another process contributing to the generation of NH_3 is the respiratory reduction of NO_3^- to NH_3 , called *dissimilative nitrate reduction to ammonia* (DNRA, Figure 21.9). DNRA dominates NO_3^- and nitrite (NO_2^-) reduction in electron donor-rich anoxic environments, such as highly organic marine sediments and the human gastrointestinal tract. Nitrate-reducing bacteria exploit this pathway primarily when NO_3^- is limiting because DNRA consumes eight electrons per NO_3^- reduced compared with the four and five electrons consumed when NO_3^- is reduced to N_2O or N_2 , respectively.

At neutral pH, NH_3 exists as ammonium (NH_4^+). Much of the NH_4^+ released by aerobic decomposition in soils is rapidly recycled and converted to amino acids in plants and microorganisms. However, because NH_3 is volatile, some of it can be lost from alkaline soils by vaporization, and major losses of NH_3 to the atmosphere

Key Processes and Microbes in the Nitrogen Cycle

Figure 21.9 Redox cycle for nitrogen. The complete anammox reaction is $\text{NH}_4^+ + \text{NO}_2^- \rightarrow \text{N}_2 + 2 \text{H}_2\text{O}$ (◀ Figure 14.26). DNRA, dissimilative nitrate reduction to ammonia.

occur in areas with dense animal populations (for example, cattle feedlots). On a global basis, however, NH_3 constitutes only about 15% of the N released to the atmosphere, the rest being primarily N_2 or N_2O from denitrification.

Nitrification

Nitrification, the oxidation of NH_3 to NO_3^- , is a major process in well-drained oxic soils at neutral pH and is carried out by the nitrifying *Bacteria* and *Archaea* (Figure 21.9). Whereas denitrification consumes NO_3^- , nitrification produces NO_3^- . If materials high in NH_3 , such as manure or sewage, are added to soils, the rate of nitrification increases.

Nitrification was long considered an obligatory two-step process in which some species oxidize NH_3 to NO_2^- and then other species oxidize NO_2^- to NO_3^- . Many species of both *Bacteria* and *Archaea* can oxidize NH_3 (◀ Sections 14.9, 15.10, 17.5), whereas only species of *Bacteria* are known that oxidize NO_2^- . However, some *Bacteria*, such as certain *Nitrospira* species, can oxidize ammonia completely to nitrate; these have been called *comammox* (for complete ammonia oxidizer) bacteria and seem to be especially important nitrifiers in freshwater lakes and rivers, drinking water systems, coastal sediments, and paddy soils.

Although NO_3^- is readily assimilated by plants, it is soluble and therefore rapidly leached (or denitrified) from waterlogged soils; consequently, nitrification is not beneficial for plant agriculture. Ammonium, on the other hand, is positively charged and strongly adsorbed to negatively charged soils. Anhydrous NH_3 is therefore used extensively as an agricultural fertilizer, but to prevent its conversion to NO_3^- by nitrification, chemicals are added to the NH_3 to

inhibit the process. One common inhibitor is a pyridine compound called *nitrapyrin* (2-chloro-6-trichloromethylpyridine). Nitrapyrin specifically inhibits the *first* step in nitrification, the oxidation of NH_3 to NO_2^- . However, this effectively halts both steps in nitrification because the second step, $\text{NO}_2^- \rightarrow \text{NO}_3^-$, depends on the first (◀ Section 14.9). The addition of nitrapyrin to anhydrous NH_3 has greatly increased the efficiency of crop fertilization and has helped prevent pollution of waterways by NO_3^- leached from nitrified soils.

Anammox

In addition to oxygen-dependent nitrification, ammonia can be oxidized under anoxic conditions in a process called *anammox* (◀ Section 14.10). Anammox bacteria affiliate with five genera (*Brocadia*, *Kuenenia*, *Scalindua*, *Anammoxoglobus*, and *Jettenia*) in a single phylogenetically cohesive family (*Brocadiaceae*) within the *Planctomycetes* (◀ Section 16.16). Since anammox bacteria have yet to be isolated in pure culture, the genus and species names are prefaced by the term *Candidatus* to indicate their tentative taxonomic status (◀ Section 13.12).

In the anammox reaction, NH_3 is oxidized anaerobically with NO_2^- as the electron acceptor, forming N_2 as the final product (Figure 21.9; ◀ Figure 14.26c), which is released to the atmosphere. Although a major process in sewage and in anoxic marine basins and sediments, anammox is not a significant process in well-drained (oxic) soils. However, in wastewater processing plants (▶ Section 22.8 and Figure 22.22), anammox is highly beneficial because like denitrification, it removes fixed nitrogen from sewage and reduces the ability of wastewater effluents to trigger algal and other microbial blooms (◀ Figure 20.19a).

Check Your Understanding

- What is nitrogen fixation and why is it important to the nitrogen cycle?
- How do the processes of nitrification and denitrification differ? How do nitrification and anammox differ?
- How does denitrification impact arable land?

21.4 The Sulfur Cycle

Microbial transformations of sulfur (S) are more complex than those of N because of the large number of oxidation states of S and the fact that several transformations of S also occur spontaneously (abiotically). The major reactions of the sulfur cycle—sulfide oxidation and sulfate (SO_4^{2-}) reduction—were covered in Sections 14.7, 14.12, 15.11, and 15.12. The redox cycle for microbial sulfur transformations is shown in **Figure 21.10**.

Although a number of oxidation states of S are possible, only three are significant in nature: -2 (sulfhydryl, R-SH ; and sulfide, HS^-), 0 (elemental sulfur, S^0), and $+6$ (sulfate, SO_4^{2-}). The bulk of S on Earth resides in sediments and rocks in the form of sulfate minerals, primarily gypsum (CaSO_4), and sulfide minerals (pyrite, FeS_2), but the oceans constitute the most significant reservoir of SO_4^{2-} in the biosphere. A significant amount of S, in particular sulfur dioxide (SO_2 , a gas), enters the S cycle from human activities, primarily from the combustion of fossil fuels, especially coal.

Hydrogen Sulfide and Sulfate Reduction

Hydrogen sulfide (H_2S) is a major volatile sulfur compound. Hydrogen sulfide is produced from bacterial sulfate reduction ($\text{SO}_4^{2-} + 4 \text{H}_2 \rightarrow \text{H}_2\text{S} + 2 \text{H}_2\text{O} + 2 \text{OH}^-$) (Figure 21.10) or emitted from sulfide springs and volcanoes. Although H_2S is volatile, different forms exist depending on pH: H_2S predominates below pH 7,

and the nonvolatile HS^- and S^{2-} predominate above pH 7. Collectively, H_2S , HS^- , and S^{2-} are referred to as “sulfide.”

Sulfate-reducing bacteria are a large and highly diverse group (◀ Sections 14.12 and 15.11) and are widespread in nature. However, in anoxic habitats such as freshwater sediments and many soils, sulfate reduction is limited by SO_4^{2-} availability. Moreover, because organic electron donors (or H_2 , which is a product of the fermentation of organic compounds) are needed to support sulfate reduction, it only occurs where significant amounts of organic material are present.

In marine sediments, the rate of sulfate reduction is typically carbon-limited and can be greatly increased by an influx of organic matter. This is important because the disposal of sewage or garbage in the oceans or coastal regions can trigger sulfate reduction. Hydrogen sulfide is toxic to many plants and animals and therefore its formation is potentially detrimental; sulfide is toxic because it combines with the iron of cytochromes and blocks respiration. Sulfide is commonly detoxified in nature by combination with iron, forming the insoluble minerals FeS (pyrrhotite) and FeS_2 (pyrite). The black color of sulfidic sediments or sulfate-reducing bacterial cultures (◀ Figure 15.28g) is due to these metal sulfide minerals.

Sulfide and Elemental Sulfur Oxidation–Reduction

Under oxic conditions, sulfide rapidly oxidizes spontaneously at neutral pH. Sulfur-oxidizing chemolithotrophic bacteria, most of which are aerobes (◀ Sections 14.7 and 15.12), can catalyze the oxidation of sulfide. However, because of the rather rapid spontaneous reaction, microbial sulfide oxidation is significant only in areas where H_2S emerging from anoxic environments meets the atmosphere. Where light is available, there can be anoxic oxidation of sulfide, catalyzed by the phototrophic purple and green sulfur bacteria (◀ Sections 14.5, 15.4, and 15.6).

Key Processes and Microbes in the Sulfur Cycle	
Process	Example organisms
Sulfide/sulfur oxidation ($\text{H}_2\text{S} \rightarrow \text{S}^0 \rightarrow \text{SO}_4^{2-}$)	Aerobic Sulfur chemolithotrophs (<i>Thiobacillus</i> , <i>Beggiatoa</i> , many others)
	Anaerobic Purple and green phototrophic bacteria, some chemolithotrophs
Sulfate reduction (anaerobic) ($\text{SO}_4^{2-} \rightarrow \text{H}_2\text{S}$)	<i>Desulfovibrio</i> , <i>Desulfobacter</i> <i>Archaeoglobus</i> (Archaea)
Sulfur reduction (anaerobic) ($\text{S}^0 \rightarrow \text{H}_2\text{S}$)	<i>Desulfuromonas</i> , many hyperthermophilic <i>Archaea</i>
Sulfur disproportionation ($\text{S}_2\text{O}_3^{2-} \rightarrow \text{H}_2\text{S} + \text{SO}_4^{2-}$)	<i>Desulfovibrio</i> , and others
Organic sulfur compound oxidation or reduction ($\text{CH}_3\text{SH} \rightarrow \text{CO}_2 + \text{H}_2\text{S}$) ($\text{DMSO} \rightarrow \text{DMS}$)	Many organisms can do this
Desulfurylation (organic-S $\rightarrow \text{H}_2\text{S}$)	Many organisms can do this

Figure 21.10 Redox cycle for sulfur. DMS, dimethyl sulfide; DMSO, dimethyl sulfoxide.

S^0 is chemically stable but is readily oxidized by sulfur-oxidizing chemolithotrophic bacteria such as *Thiobacillus* and *Acidithiobacillus*. Because S^0 is insoluble, the bacteria that oxidize it must attach to the S^0 crystals to obtain their substrate (◀ Figure 14.19). The oxidation of S^0 forms sulfuric acid (H_2SO_4), and thus S^0 oxidation characteristically lowers the pH in the environment, sometimes drastically. For this reason, small amounts of S^0 can be added to alkaline agricultural soils as an inexpensive and natural way to lower the pH, relying on the ubiquitous sulfur chemolithotrophs to carry out the acidification process.

S^0 can be reduced as well as oxidized. The reduction of S^0 to sulfide (a form of anaerobic respiration) is a major ecological process of some *Bacteria* and hyperthermophilic *Archaea* (Chapter 17). Although sulfate-reducing bacteria can also reduce S^0 , most S^0 reduction in nature occurs by the activities of the physiologically specialized sulfur reducers, organisms that are incapable of SO_4^{2-} reduction (◀ Section 15.11). However, the habitats of the sulfur reducers are generally those of the sulfate reducers, so from an ecological standpoint, the two groups form a metabolic guild unified by their formation of H_2S .

Organic Sulfur Compounds

In addition to *inorganic* forms of S, multiple forms of *organic* S compounds are also cycled in nature. Many of these foul-smelling compounds are highly volatile and can thus enter the atmosphere. Hundreds of different dissolved organic sulfur compounds have been identified in surface waters of the oceans. Many of these are rapidly cycled and are increasingly thought to play important roles in ecosystem dynamics. However, only a handful have been fully chemically characterized.

The most abundant organic S compound in nature is *dimethyl sulfide* [DMS, $(CH_3)_2S$]; it is produced primarily in marine environments as a degradation product of dimethylsulfoniopropionate [DMSP], a major osmoregulatory solute in marine algae (◀ Section 4.15). As described previously (◀ Section 20.12), DMSP is catabolized by marine bacteria yielding DMS; in the atmosphere, DMS becomes photooxidized to sulfate, and this promotes the formation of clouds that help cool our planet (Section 21.9).

By contrast, DMS produced in anoxic habitats can be microbially transformed in at least three ways: (1) by methanogenesis (yielding CH_4 and H_2S), (2) as an electron donor for CO_2 fixation by certain phototrophic purple bacteria (yielding dimethyl sulfoxide, DMSO), and (3) as an electron donor in energy metabolism in certain chemooorganotrophs and chemolithotrophs (also yielding DMSO). DMSO can be an electron acceptor for anaerobic respiration (◀ Section 14.13), producing DMS. Many other organic S compounds affect the global sulfur cycle, including methanethiol (CH_3SH), dimethyl disulfide (CH_3SSCH_3), and carbon disulfide (CS_2), but on a global basis, DMS is the most significant.

Check Your Understanding

- Is H_2S a substrate or a product of the sulfate-reducing bacteria? Of the chemolithotrophic sulfur bacteria?
- What is the difference between chemotrophic and phototrophic sulfur oxidation?
- What organic sulfur compound is most abundant in nature, and how does it help keep Earth cool?

II • Other Nutrient Cycles

In addition to cycling major elements, microbes cycle many minor elements required for life—such as iron and phosphorus—as well as silicon and calcium required by certain marine phototrophs. Novel mechanisms of electron transfer are employed by microbes whose electron donors and acceptors are spatially distinct.

In Part II of this chapter we explore the interactions of microorganisms with metals—in particular the major processes of iron and manganese cycling—and with some nonmetals whose microbial transformations are also of major global significance.

21.5 The Iron and Manganese Cycles: Reductive Activities

Iron (Fe) is one of the most abundant elements in Earth's crust. On the surface of Earth, Fe exists naturally in two oxidation states, ferrous [Fe^{2+} , also Fe(II)] and ferric [Fe^{3+} , also Fe(III)]. A third oxidation state, Fe^0 , is abundant in Earth's core and is also a major product of human activities from the smelting of iron ores to form cast iron.

In nature, iron cycles primarily between the Fe^{2+} and Fe^{3+} forms, and these redox transitions are one-electron oxidations and reductions. Ferric iron is reduced both chemically and as a form of anaerobic respiration, and Fe^{2+} is oxidized both chemically and as a form of chemolithotrophic metabolism (Figure 21.11). Manganese (Mn), although present at 5- to 10-fold lesser abundance than Fe in the near-surface environment, is another redox-active metal of microbiological significance, existing primarily in two oxidation states (Mn^{2+} and Mn^{4+} , see Figure 21.12).

Figure 21.11 Redox cycle for iron. The major forms of iron in nature are Fe^{2+} and Fe^{3+} . Fe^0 is primarily a product of smelting of iron ores. Fe^{3+} forms various minerals such as ferric hydroxide, $Fe(OH)_3$.

A key feature of the iron and manganese cycles is the different solubilities of these metals in their oxidized versus reduced forms. Reduced iron (Fe^{2+}) and manganese (Mn^{2+}) are soluble. In contrast, oxidized minerals of iron such as iron oxide-hydroxides [e.g., $\text{Fe}(\text{OH})_3$, FeOOH , and Fe_2O_3] and manganese oxide (MnO_2) are insoluble and tend to settle out in aquatic environments. As a consequence, these strong oxidants can comprise several percent by weight of marine and freshwater sediments, making them among the most abundant of potential electron acceptors in many anoxic systems (see Figure 21.12).

Bacterial Reduction of Iron and Manganese Oxides

Some *Bacteria* and *Archaea* can use Fe^{3+} as an electron acceptor in anaerobic respiration (◀ Section 15.13). These organisms also commonly have the capacity to use Mn^{4+} as an electron acceptor, and some have the capacity to reduce oxidized uranium (▶ Section 22.3). Ferric iron and manganese oxide reduction is common in water-logged soils, bogs, and anoxic lake sediments (Figure 21.12). When soluble reduced iron and manganese reach oxic regions, for example, through diffusion from anoxic regions of sediments, they are oxidized chemically [e.g., $\text{Fe}^{2+} + \frac{1}{4}\text{O}_2 + 2\frac{1}{2}\text{H}_2\text{O} \rightarrow \text{Fe}(\text{OH})_3 + 2\text{H}^+$] or microbially (Figure 21.12). The chemical oxidation of Fe^{2+} is very rapid at near-neutral pH. Although the spontaneous oxidation of Mn^{2+} is very slow at neutral pH, the rate of oxidation can be increased up to five orders of magnitude by a variety of manganese-oxidizing bacteria and even fungi. The oxidized metal oxides and hydroxides then precipitate, returning the oxidized metals to the sediments where they can again serve as electron acceptors, completing the cycle.

Oxidized iron (Fe^{3+}) and manganese (Mn^{4+}) are chemically very reactive and can alter the availability of both nutrients and toxic metals. For example, phosphate is less available when it is trapped as insoluble ferric phosphate precipitates. Essential and toxic metals [e.g., copper (Cu), cadmium (Cd), cobalt (Co), lead (Pb), and

arsenic (As)] also form insoluble complexes with iron and manganese oxides. When these oxides are subsequently microbially reduced, the bound phosphate is liberated along with the soluble forms of these metals. In addition to sequestering phosphate and metals, abiotic oxidation of refractory organic compounds by manganese oxide may yield more available sources of carbon for microbial growth.

Long-Range Electron Transfer to Insoluble Electron Acceptors

As we learned earlier (Chapters 3 and 14), in any form of respiration, electron disposal is necessary for energy conservation. When the electron acceptor is oxygen (O_2), nitrate (NO_3^-), or many other soluble substances used by bacteria as electron acceptors (◀ Sections 14.11–14.15), the final product diffuses away from the cell. Many bacteria reduce ferric iron (Fe^{3+}) as an electron acceptor under anoxic conditions, including the obligate anaerobe *Geobacter sulfurreducens* and the facultative aerobe *Shewanella oneidensis*. However, in contrast to soluble electron acceptors, Fe^{3+} is typically present in nature as an insoluble mineral, such as an iron oxide, and thus the reduction of Fe^{3+} must occur *outside* the cell. Under such conditions, the ferric iron functions as an electrical anode, and the bacterial cell facilitates transfer of electrons from the electron donor to the anode.

Regardless of the electron acceptor they use, when bacteria respire, they carry out oxidations and reductions that generate electricity. Thus, the surfaces and appendages of cells of bacteria that interact with iron and manganese oxides, such as *Geobacter* (Figure 21.13a), are electrically conductive. *Geobacter* forms direct electrical connections with insoluble materials that can either accept or donate electrons. Electron transfer employs cytochromes localized along the length of pili that are generally 10–20 micrometers long (◀ Figure 14.31). These electrically conductive structures function as electrical nanowires, much as copper wires do in a household electrical circuit. Being conductive structures, nanowires can form direct electrical connections with insoluble materials that either accept or donate electrons; alternatively, nanowires can form connections between cells. In this way, electrons obtained by *Geobacter* from the oxidation of organic electron donors or from H_2 can be shuttled to a suitable electron acceptor.

Some electron transfers can occur over rather long distances, even longer than the cell itself. For example, hydrogen sulfide (H_2S) oxidation in some anoxic marine sediments is facilitated by filamentous bacteria composed of many interconnected cells that transfer electrons from sulfide (the donor) in the sediments to O_2 (the acceptor) in the overlying water, a distance of 2.5 cm (25000 μm , Figure 21.13b, c). The surface of the filamentous cells has ridges running along its entire length, and each microbial filament is surrounded by 15 to 17 such structures (Figure 21.13b). The structures function as electrical cables to transfer electrons from the sulfide oxidized at one end of the filament to the reduction of O_2 at the other end of the filament.

As for *Geobacter*, *Shewanella* is also capable of direct transfer of electrons to an insoluble exogenous electron acceptor. However, unlike *Geobacter* with its use of conductive pili, *Shewanella* uses cytochrome-rich extensions of its outer membrane to make physical

Figure 21.12 Iron and manganese redox cycling in a typical freshwater system. Iron and manganese oxides in sediments are used as electron acceptors by metal-reducing bacteria. The resulting reduced forms are soluble and diffuse into the oxic regions of the sediment or water column, where they are oxidized microbially or chemically. Precipitation of the insoluble oxidized metals then returns the metals to the sediments, completing the redox cycle.

Figure 21.13 Direct and long-range electron transfer. (a) Cells of *Geobacter* attached to ferric iron precipitates (arrows) reduce Fe^{3+} to Fe^{2+} . (b) Three-dimensional rendering of cabled filamentous sulfide-oxidizers, with inset transmission electron microscopical cross-section displaying presumptive electrically conductive filaments surrounding the cell perimeter. (c) Microsensor profiles of sediments colonized by cabled filamentous bacteria, showing wide separation of depths where sulfide oxidation and oxygen reduction occur. The profiles are explained as follows: Oxygen (O_2) is quickly consumed by bacterial respiration in the upper regions of the sediment, whereas H_2S , produced in anoxic regions, only accumulates deeper in the sediments. The pH is more acidic lower in the sediments because sulfide oxidation yields protons. As O_2 is consumed near the sediment surface, protons are also consumed, and the pH rises.

contact with a mineral surface such as iron oxide. This system couples transfer of electrons, obtained from the oxidation of lactate or other organic compounds, to soluble cytochromes in the cell's periplasm and then to the cell surface using the Mtr complex of membrane-spanning multiheme proteins (Figure 21.14). From the Mtr complex, electrons can be shuttled (see next subsection) to the iron oxide by way of FMN (an electron carrier, ◀ Section 3.8) or directly transferred from MtrC, the outermost part of the Mtr protein complex, to iron oxide. An electrode poised at an electropositive potential can also function as an electron acceptor for this organism (Figure 21.14).

Extracellular Electron Shuttles

Another type of extracellular electron transfer is mediated by small, soluble, redox-active molecules called *extracellular electron shuttles* (EESs), typically aromatic organic compounds. The key functional attribute of an EES is the presence of conjugated double bonds that

undergo redox transitions at a reduction potential (E_0') that facilitates transfer of electrons from the cell to an electron acceptor poised at a suitable potential difference. The acceptor can be an insoluble material such as oxidized metal or any other substance that can be reduced by the EES, including an actual electrode.

Naturally occurring humic substances (Section 21.1) often function as EESs. Since some constituents of humics can alternate between oxidized and reduced forms, they can function to shuttle electrons from the bacterium to reduce iron or manganese oxides (Figure 21.15). However, in addition to using shuttles that are available in the environment, a number of microorganisms secrete EESs to facilitate transfer of electrons to exogenous electron acceptors. These may be common cellular cofactors, such as flavin mononucleotide (FMN) secreted by *Shewanella oneidensis* (Figure 21.14), or more specialized shuttles such as the virulence factor pyocyanin (Figure 21.16a), a derivative of phenazine, made by *Pseudomonas aeruginosa*. Pyocyanin has many effects, including enhancing

Figure 21.14 *Shewanella* electron transfer to insoluble electron acceptors. Electrons from lactate oxidation enter the quinone pool (Q, QH₂) through a membrane-bound NADH dehydrogenase. Reduced quinone (QH₂) is oxidized by a membrane-associated multiheme cytochrome (CymA), which transfers electrons to the outer membrane-spanning Mtr complex via periplasmic c-type cytochromes. The outer part of the Mtr complex (MtrC) then delivers electrons to an insoluble electron acceptor via direct interaction, such as to an iron oxide or an electrode, or via flavin (FMN) electron shuttles. FMNs are actively secreted by *Shewanella*. Although some proton efflux may be associated with electron transfer to CymA, ATP generation is primarily by substrate-level phosphorylation.

substrate-level ATP synthesis by oxidizing excess intracellular redox cofactors such as NADH, promoting biofilm formation, generating peroxide by reduction of molecular oxygen, and a capacity to liberate ferrous iron from an infected host's iron reserves. Pyocyanin is present in the lungs of patients suffering from the genetic disease

Figure 21.15 Role of humic substances in humus as an electron shuttle in microbial metal reduction. Quinone-like functional groups in humus are reduced by acetate-oxidizing bacteria. The reduced humus then donates electrons to metal oxides, releasing reduced iron (Fe²⁺) and oxidized humus. The cycle continues as oxidized humus is again reduced by the bacteria.

cystic fibrosis, where vigorous biofilms of this bacterium develop (Section 8.10); maintenance of the bacterial infection is promoted in part by the organism's ability to reduce ferric iron to the soluble ferrous form and sequester it through activity of the Feo iron transport membrane protein (Figure 21.16b).

Both direct electron transfer (as seen in Section 23.3) and the use of EESs are also important for transfer of electrons between symbiotically associated microorganisms. In nature, electrical communication between bacterial cells may be a major way by which electrons generated from microbial metabolism in anoxic habitats are shuttled to oxic regions. Moreover, research on the microbiology of the process indicates that this microbial electricity could be harnessed in the form of microbial "fuel cells" that could oxidize toxic and waste carbon compounds in anoxic environments, with the resulting electrons coupled to power generation. In such a scheme, bacteria would be exploited to function as catalysts for diverting electrons from electron donors directly to artificial anodes (Figure 21.14), with the resulting electrical current being siphoned off to supply a portion of human power needs. Such a system would have to be developed on a very large scale, of course. However, large-scale systems for microbial growth are already well established in wastewater treatment facilities (Sections 22.6–22.8).

Figure 21.16 Pyocyanin electron shuttling. (a) Pyocyanin undergoes single and double electron transfer reactions between cells and environmentally available electron acceptors. (b) In *Pseudomonas* species, the pyocyanin electron shuttle is a virulence factor, the reduced pyocyanin functioning to reduce ferric iron to acquire iron from the infected host and incorporate it through the Feo uptake system.

Check Your Understanding

- In what oxidation states are Fe in $\text{Fe}(\text{OH})_3$ and Mn in MnO_2 ?
- What alternative mechanisms are used by iron-respiring microorganism to deliver electrons to insoluble electron acceptors?

21.6 The Iron and Manganese Cycles: Oxidative Activities

Besides functioning as electron *acceptors* in their oxidized forms, in their reduced forms, iron and manganese can also function as electron *donors* (◀ Section 14.8). In this section, we explore this option as important links in the iron and manganese cycles.

Microbial Oxidation of Reduced Iron

At neutral pH, ferrous iron (Fe^{2+}) is oxidized abiotically in oxic environments. By contrast, at *acidic* pH ($\text{pH} < 4$), Fe^{2+} is not oxidized spontaneously. Thus, much of the research on microbial oxidation of iron has been focused on acidic, ferrous-iron-rich habitats, where acidophilic chemolithotrophs such as *Acidithiobacillus ferrooxidans* and *Leptospirillum ferrooxidans* oxidize Fe^{2+} to Fe^{3+} (Figure 21.17). As we will see in Chapter 22, this activity can be both beneficial and harmful. On the one hand, because the oxidation of ferrous iron generates acidity, this can be devastating if large amounts of iron and other metal sulfides are released into freshwaters or soils, such as from mining activities. The acidity produced from iron oxidation can make the environments unsuitable for plant and animal life (▶ Figure 22.5). On the other hand, the generation of acidity and the ability of acidophilic chemolithotrophs to oxidize ferrous iron is exploited in the mining industry to extract metals such as copper from low-grade ores (▶ Section 22.1 and Figure 22.2).

Figure 21.17 Oxidation of ferrous iron (Fe^{2+}). A microbial mat growing in the Rio Tinto, Spain. The mat consists of acidophilic green algae (eukaryotes) and various iron-oxidizing chemolithotrophic bacteria. The Rio Tinto has a pH of about 2 and contains high levels of dissolved metals, in particular Fe^{2+} . The red-brown precipitates consist of $\text{Fe}(\text{OH})_3$ and other ferric minerals.

In addition to oxidation by acidophilic microorganisms, ferrous iron can be oxidized microbially at neutral pH. However, since the abiotic oxidation of reduced iron also occurs under these conditions, iron-oxidizing bacteria that inhabit nonacidic environments are restricted to a very narrow zone in which anoxic ferrous-iron-rich water mixes with oxygenated water. These microoxic habitats include freshwater and coastal sediments (Figure 21.12; ◀ Figure 20.22), seeps of iron-rich groundwater, slow-moving streams, ferrous-iron-rich waters from springs, and hydrothermal vents (Figure 21.18). When ferrous-iron-rich groundwaters are exposed to air, Fe^{2+} is oxidized at the interface of these two zones by iron-oxidizing bacteria such as *Leptothrix* and *Gallionella* (Figure 21.18b, c, d; ◀ Sections 14.8 and 15.14). Thus, their physiology dictates that they maintain a position within a narrow environment of low levels of O_2 and high levels of reduced metals. Although O_2 is the most environmentally significant electron acceptor, Fe^{2+} oxidation can also be coupled to NO_3^- reduction by some anaerobic microbes (◀ Sections 14.8 and 15.14), and Fe^{2+} functions as an electron donor in photosynthesis for some anoxygenic phototrophs (◀ Sections 14.5, 15.2, and 15.5). Neutrophilic aerobic iron-oxidizing bacteria are members of two proteobacterial classes. The freshwater species are members of several closely related genera in the *Betaproteobacteria* whereas all known marine species are *Zetaproteobacteria* (*Proteobacteria* are discussed in Chapter 16). All characterized *Zetaproteobacteria* are autotrophic and aerobic iron-oxidizers, and all but the bacterium *Ghiorea bivora*—which can oxidize either Fe^{2+} or H_2 as electron donors—are obligate iron-oxidizers. Although primarily associated with marine environments, the *Zetaproteobacteria* have also been found in saline terrestrial aquifers and springs, and in biofilms associated with steel corrosion (▶ Section 22.12).

As we saw in Section 21.5, organisms that reduce insoluble metal oxides can use extracellular conductors for electron transfer, such as electrically conductive pili or cell-surface-associated cytochromes. Cytochromes participate in both iron reduction and iron oxidation, and genomes of metal-oxidizing *Gallionella* and *Sideroxydans* species contain genes encoding periplasmic *c*-type cytochromes that resemble those encoding proteins known to reduce metal oxides in *Shewanella* (Figure 21.14), indicating that mechanistically related electron transfer pathways are used for both the reduction and oxidation of extracellular metals.

Although possibly sharing similar electron transfer mechanisms, metal-oxidizing bacteria are confronted with the problem that the precipitates they form can encase the cell in an iron oxide shell. To prevent this, metal oxidizers secrete organic substances that capture metal oxides and deposit them some distance away from the cell. For example, the iron oxidizer *Gallionella* produces extended organic stalks that become encrusted with metal oxides away from the cell (Figure 21.18d, f, and g; see also Figure 15.36). Similar structures are made by marine *Zetaproteobacteria* of the genus *Mariprofundus*; the species *Mariprofundus ferrooxydans* deposits iron oxides as a twisted stalk while *Mariprofundus ferrinatatus* makes shorter ropelike filaments of iron oxides (Figure 21.19). Laboratory experiments employing opposing gradients of Fe^{2+} and O_2 showed that *M. ferrooxydans* uses its iron oxide stalk as both a holdfast and a dynamic structure to position cells at an optimum point within the gradient of oxygen and Fe^{2+} . An alternative strategy is used by *Leptothrix* and *Sphaerotilus*

Figure 21.18 Fe-oxidizing microbial mats. ochracea (the sheath is approximately $2\ \mu\text{m}$ wide). (d) The stalk-forming Fe^{2+} -oxidizer *Gallionella ferruginea* showing bean-shaped cells in the process of cell division at the end of the iron oxide-encrusted stalk (each bean-shaped cell is about $2\ \mu\text{m}$ long). (e) An iron-oxidizing mat at a deep-sea hydrothermal vent (1000-meter depth) at Lō'ihi Seamount. (f) TEM image of biogenic

oxides produced at Lō'ihi; note the variety of helical stalks and tubular sheathlike filaments (the filaments vary from 2 to $4\ \mu\text{m}$ wide). (g) Phase-contrast photomicrograph of marine Fe^{2+} -oxidizers growing at the ends of iron oxide filaments (cells denoted by arrows) from an experimental incubation at Lō'ihi (filaments are approximately $2\ \mu\text{m}$ wide).

species. These bacteria produce an organic sheath surrounding the cells that becomes encrusted with metal oxides (Figure 21.18b and ◀ Figure 15.55). Later, the cells move out of the sheath, leaving the metal oxide crust behind. Although not all metal oxidizers produce such morphologically conspicuous structures, it is thought that most, if not all, metal oxidizers are forced to produce some form of extracellular organic material in order to sequester the insoluble product of their energy metabolism.

Microbial Oxidation of Reduced Manganese

Many bacteria catalyze Mn^{2+} oxidation, and the different species known are ubiquitous in nature, inhabiting fresh and marine waters, soils, and virtually anywhere significant levels of Mn^{2+} are present. Reduced manganese is present along with Fe^{2+} in anoxic waters that reach oxic zones, the Mn^{2+} resulting from the anaerobic respiration of Mn^{4+} (Figure 21.12; ◀ Figure 20.22); these anoxic/oxic interfaces

establish a niche for the obligately aerobic Mn^{2+} -oxidizing bacteria. Because the reduction potential of the $\text{Mn}^{2+}/\text{Mn}^{4+}$ couple is so high, very near to that of the $\text{O}_2/\text{H}_2\text{O}$ couple (◀ Figure 14.1), O_2 is the only electron acceptor that can couple with Mn^{2+} oxidation; anaerobic respirations of Mn^{2+} are thus not possible.

Several genera of *Bacteria* can oxidize Mn^{2+} including *Sphaerotilus* and *Leptothrix*—both *Betaproteobacteria*—and *Hyphomicrobium* and *Pedomicrobium*—both *Alphaproteobacteria* (◀ Figures 15.51, 15.55, and 15.56). Some *Pseudomonas* species can also oxidize Mn^{2+} . Most of these organisms can be cultured and therefore Mn^{2+} oxidation easily measured. However, a major unanswered question surrounding this entire physiological group is whether they actually benefit from Mn^{2+} oxidation. Chemolithotrophic (and autotrophic) growth on Mn^{2+} has been achieved with one *Pseudomonas* species whose cells were shown to contain carboxysomes (◀ Figure 15.30a). Carboxysomes are storage granules of the key enzymes of the Calvin

(b) *Mariprofundus ferrinatatus* forms short iron oxide structures (colorized red), which are shed from the single cell (outlined in yellow) that is covered by the mineral deposits. The cell is about 1 μm long. Images reproduced from McAllister, S.M., Moore, R.M., Gartman, A., Luther, G.W., III, Emerson, D., and C.S. Chan. 2019 *FEMS Microbiol. Ecol.* doi:10.1093/femsec/fiz015.

cycle (◀ Section 3.12), the main autotrophic pathway of aerobic chemolithotrophs. Convincing chemolithotrophic growth of other species of Mn^{2+} oxidizers has not been achieved. A possible alternative reason for Mn^{2+} oxidation is to convert soluble Mn^{2+} —which can be a toxic metal when present in high enough concentrations—into nontoxic manganese oxides. Whatever the reason(s) for bacterial Mn^{2+} oxidation, the process can be a major one in nature and is typically linked to neutral pH habitats where extensive iron oxidation is occurring simultaneously.

Check Your Understanding

- Both *Acidithiobacillus* and *Mariprofundus* are iron oxidizers, but their habitats differ dramatically. Explain.
- Although some iron-oxidizing bacteria can grow on iron anaerobically, manganese-oxidizing bacteria cannot grow on manganese anaerobically. Explain.

21.7 The Phosphorus, Calcium, and Silicon Cycles

Many other chemical elements undergo microbial cycling and we focus on three key ones here: phosphorus (P), calcium (Ca), and silicon (Si). The cycling of these elements is important in aquatic environments, particularly in the oceans, which are major reservoirs of Ca

and Si and where large amounts of Ca and Si are incorporated into the exoskeletons of certain microbes. However, unlike the C, N, and S cycles, in the Ca and Si cycles there are no redox changes or gaseous forms that can escape and alter Earth's atmospheric chemistry. However, different redox states of P are biogeochemically significant. From a global perspective, keeping these cycles in balance—especially that of Ca—is important for maintaining sustainable life on Earth.

Phosphorus and Phosphonates

Phosphorus exists in nature primarily as organic and inorganic phosphates. Phosphorus reservoirs include phosphate-containing minerals in rocks, dissolved phosphates in freshwaters and marine waters, and the nucleic acids and phospholipids of living organisms. Although P has multiple oxidation states, most environmental phosphates are at the +5 oxidation state (for example, hydrogen phosphate, HPO_4^{2-}). In nature, P cycles through living organisms (as cellular P), waters and soils (as inorganic and organic P), and Earth's crust (as inorganic P). P is typically the limiting nutrient for photosynthesis in freshwaters, which receive it from the weathering of rocks.

In the oceans, a fraction of dissolved P is organic, in the form of phosphate esters and *phosphonates*. Phosphonates, also referred to as *phosphonic acids* when in the protonated forms, are organophosphate compounds that contain a direct bond between the P and C atoms. In this form the P atom is more reduced (+3 oxidation state) than in phosphate (+5 oxidation state). Phosphonates are produced by certain microorganisms and comprise about a quarter of the organic P pool in nature. For many organisms, phosphonates are a less available source of P than is HPO_4^{2-} because the organisms lack the enzymes required to degrade phosphonates. Such organisms can be phosphorus-limited even when sufficient P is present as phosphonates.

Phosphonates and reduced inorganic forms of P—phosphite (H_2PO_3^- , +3 oxidation state) and hypophosphite (H_2PO_2^- , +1 oxidation state)—are rapidly cycled in the marine environment by producers and consumers. This cycling of P is important for organisms that live in P-depleted environments and have the capacity to make or consume these alternative forms of phosphorus. Why marine organisms produce so much of these reduced phosphorus species is unknown. However, the fact that some marine microorganisms produce methylphosphonic acid may have solved another marine metabolic conundrum. The degradation of methylphosphonic acid ($\text{CH}_3\text{O}_3\text{P}$) by some marine microorganisms—a process that liberates methane (CH_4)—likely explains the previously puzzling observation that relatively high levels of CH_4 are present in the oxygenated surface waters of the ocean (see Explore the Microbial World, “Solving the Marine Methane Paradox”).

Calcium

The major global reservoirs of calcium (Ca) are calcareous rocks and the oceans. In the oceans, where dissolved Ca exists as Ca^{2+} , calcium cycling is a highly dynamic process although the concentration of Ca^{2+} in seawater remains constant at about 10 mM. Several marine eukaryotic phototrophic microorganisms take up Ca^{2+} to form their calcareous exoskeletons; these include in particular species of haptophytes called *coccolithophores* (◀ Section 18.7 and Figure 18.15) and *Rhizaria* called *foraminifera* (◀ Section 18.6) (Figure 21.20). The calcium-cycling activities of these planktonic phototrophs are also tightly coupled with inorganic components of the carbon cycle.

Figure 21.20 The marine calcium cycle. Scanning electron micrographs of cells of the calcareous phytoplankton (a) *Emiliania huxleyi* and (b) *Discosphaera tubifera*. The exoskeletons of these coccolithophores are made of calcium carbonate (CaCO_3). A cell of *E. huxleyi* is about $8 \mu\text{m}$ wide and a cell of *D. tubifera* is about $12 \mu\text{m}$ wide. (c) The marine calcium cycle; dynamic pools of Ca are shaded in green. Detrital CaCO_3 is that in fecal pellets and other organic matter from dead organisms. Note how H_2CO_3 formation lowers ocean pH when it dissociates to form H^+ and HCO_3^- .

The precipitation of calcium carbonate (CaCO_3) to form the shells of calcareous phytoplankton controls both CO_2 flux into ocean surface water and inorganic C transport into deep ocean waters and the sediments. Moreover, the formation of CaCO_3 both depletes surface dissolved bicarbonate (HCO_3^-) and increases the level of dissolved CO_2 (Figure 21.20c). The latter reduces the influx of atmospheric CO_2 into surface ocean waters, and this helps maintain the slightly alkaline pH of the oceans. When these calcareous organisms die and sink toward the sediments, Ca^{2+} and inorganic C are transported to the deep ocean from which they are only slowly released over long periods (see also page 621).

The formation of CaCO_3 exoskeletons brings into play a delicate balance between Ca^{2+} and C and is a process sensitive to changes in atmospheric CO_2 levels. This is because increased levels of atmospheric CO_2 increase the formation of carbonic acid (H_2CO_3), and as this dissociates to form HCO_3^- and H^+ , CaCO_3 dissolves and seawater pH decreases (Figure 21.20c). Greater ocean acidity resulting from rising atmospheric CO_2 is predicted to reduce the rate of formation of calcareous shells, which will likely have effects on other microbial nutrient cycles and plant and animal communities (Section 21.9).

Silicon

The marine Si cycle is controlled primarily by unicellular eukaryotes (diatoms and other *Stramenopiles* referred to as silicoflagellates, and radiolarians) that build ornate external cell skeletons called *frustules* (diatoms, Figure 21.21a; Section 18.5 and Figure 18.12) or tests (radiolarians, Section 18.6). These structures are not constructed of CaCO_3 as in the coccolithophores, but of silica (SiO_2 , also called opal), whose formation begins with the uptake by the cell of dissolved silicic acid (Figure 21.21b).

Diatoms are rapidly growing phototrophic eukaryotes and often dominate blooms of phytoplankton in coastal and open ocean waters. However, unlike other major phytoplankton groups, diatoms require Si and can become silicon-limited when blooms develop. Also, because of their large size, diatom cells tend to sink faster than other organic particles, and in this way, they contribute significantly to the return of Si and C to deeper ocean waters. The transport of organic material produced through primary production in near-surface waters to deeper ocean waters, primarily by sinking particles, is called the *biological pump* and is an important aspect of the carbon cycle in terms of carbon burial and mineralization in marine environments (Figure 21.1).

In addition to the major nutrient requirements of any phototrophic organism (CO_2 , N, P, Fe), diatoms require sufficient dissolved Si, and in nature this originates primarily from Si released from the skeletons of dead diatoms (Figure 21.21b). Although Si is released fairly rapidly

Solving the Marine Methane Paradox

An anomaly in the concentration of dissolved methane in oxygenated ocean surface waters was first observed in the latter half of the last century. A region from the surface to approximately 300 meters depth is supersaturated in methane relative to the concentration expected if the ocean was in equilibrium with atmospheric methane (Figure 1a). About 75% of the oceanic flux of methane to the atmosphere derives from this source (other sources being melting methane hydrates and methane generated in marine sediments; see Figures 21.3, 21.4, and 21.5). Because methane is a major greenhouse gas (Section 21.9), identifying its marine origins has been considered essential for predicting how changes in ocean temperatures might exacerbate climate change.

An initial clue came from the light isotopic composition of carbon in methane from marine surface waters, a result consistent with a microbial source (Section 19.10). However, this presented a conundrum—only obligately *anaerobic* methanogens are known to produce methane (Section 17.2), and marine surface waters are highly oxic. Thus, at first glance, a microbial source for this methane did not make sense. However, a solution to this paradox ultimately came from studies of the marine phosphorus cycle.

Dissolved phosphorus, often a limiting nutrient controlling primary production in the ocean, is present in both inorganic (typically as

phosphate) and organic forms. About 10% of the dissolved organic phosphorus is in the form of phosphonates, compounds characterized by a C–P bond (Figure 1b, c). About 10% of marine microbes are capable of phosphonate biosynthesis; however, not all marine organisms are capable of using phosphonate. Cleavage of the C–P bond, required for release of inorganic phosphate, requires an enzyme called *C–P lyase*. Since phosphonates are abundant in upper ocean waters and the C–P bond can be cleaved by many marine microbes, it was hypothesized that methylphosphonate, or the protonated form methylphosphonic acid (Figure 1b), could be the source of the surface water methane observed.

Subsequent experiments showed that several aerobic marine bacteria could cleave methylphosphonate and use the released phosphate to support growth. However, this brought up another question: What was the source of the methylphosphonic acid? This riddle was solved when a pathway for its biosynthesis was discovered in the marine ammonia-oxidizing archaeon *Nitrosopumilus maritimus*¹ (Figure 1b). Identification of the biochemical pathway and supporting genes from this organism facilitated surveys of other marine microbes and marine metagenomes for similar genes. These studies revealed that the pathway for methylphosphonic acid

biosynthesis is widely distributed in marine bacteria, including the abundant chemotrophic bacterium *Pelagibacter* and phototroph *Prochlorococcus* (Sections 20.11 and 20.12).

Quantitative studies have confirmed that levels of methylphosphonate in the marine pool of dissolved organic phosphorus can account for the marine methane anomaly, solving the methane paradox and identifying an important new process in the cycling of carbon and phosphorus in the ocean.² But in addition to marine sources of phosphonates, a few phosphonates are of medical or agricultural significance, including the antibiotic fosfomycin—a potent clinical weapon for treating urinary tract infections—and the widely used herbicide glyphosate (marketed as Roundup®) (Figure 1c). Glyphosate can be catabolized as a sole source of carbon, nitrogen, and phosphate by several different bacteria. However, because of the large amounts of this herbicide used agriculturally, microbial ecological studies of glyphosate biodegradation is an area in need of much further research if we are to understand the fate of terrestrial phosphonates as well as we now do marine phosphonates.

following cell death, during periods of high diatom production in relatively shallow waters, a significant fraction of dissolved Si can become buried in sediments and remain there for millions of years. This has consequences for continued diatom growth and their phototrophic consumption of dissolved CO₂ from ocean waters. The flux of CO₂ into and out of ocean water affects its pH (Figure 21.20c), and through this link, the Si and C cycles are coupled in a manner similar to what we have seen with the Ca and C cycles (Figure 21.20).

Although the nutrient cycles we have seen thus far are mainly driven by microbial activities (plus plants in the case of the C cycle), humans can have major impacts on nutrient cycling through major inputs of C, N and toxic elements, and we consider these next.

Check Your Understanding

- How does the formation of CaCO₃ skeletons by calcareous phytoplankton retard movement of CO₂ from the atmosphere to oceans and help maintain ocean water pH?
- How might Si depletion in the photic zone influence the biological pump?

III • Humans and Nutrient Cycling

In addition to steadily increasing levels of CO₂, intensive agriculture and fossil fuel burning have increased levels of nitrous oxide and methane and have accelerated the mobilization of mercury. Human inputs into major nutrient cycles will likely affect all life forms, be they microbes, flora, or fauna.

Humans have a profound impact on microbial nutrient cycles by adding and removing specific components of the cycles in large amounts. Here we consider human inputs of three major chemical groups: mercury (Hg), CO₂ and other atmospheric gases, and various fixed N compounds. These compounds originate primarily from the burning of fossil fuels or from agricultural activities, and either cause toxicity problems (Hg) or affect Earth in globally significant ways (gases and N compounds). We begin with the very toxic metal Hg, which is transformed by bacteria in many different ways.

Figure 1 The marine methane paradox. (a) Representative profile of dissolved methane in surface waters of the Atlantic Ocean showing supersaturation of methane in the upper 300 meters. (b) The pathway for methylphosphonic acid biosynthesis, first identified in the marine ammonia-oxidizing archaeon *Nitrosopumilus maritimus* (scanning electron micrograph). Phosphoenolpyruvic acid (PEP) is an intermediate in glycolysis (◀ Section 3.6 and Figure 3.11). Methylphosphonic acid synthase (MpnS) generates the methylphosphonic acid that is subsequently cleaved to methane and inorganic phosphate by the enzyme C–P lyase present in many marine bacteria. The enzyme phosphoenolpyruvic acid mutase (PepM) catalyzes the first step of all known phosphonic acid biosynthesis pathways, and the presence of the *pepM* gene is diagnostic for organisms having the capacity for phosphonic acid biosynthesis. (c) Structures of the phosphonate antibiotic fosfomycin and the phosphonate herbicide glyphosate.

21.8 Mercury Transformations

Mercury is not a microbial nutrient (◀ Figure 4.1), but microbial transformations of various mercuric compounds are natural processes and help to detoxify some of the most toxic forms. Mercury is a widely used industrial product, especially in the electronics industry. Mercury is also an active ingredient in many pesticides, a pollutant from the chemical and mining industries and from the combustion of coal and municipal wastes, and a common contaminant of aquatic ecosystems and wetlands. Because of its propensity to concentrate in living tissues, Hg is of considerable environmental importance. The major form of Hg in the atmosphere is elemental mercury (Hg⁰), which is volatile and is oxidized to mercuric ion (Hg²⁺) photochemically. Most Hg thus enters aquatic environments as Hg²⁺ (Figure 21.22).

Microbial Redox Cycle for Mercury

Mercuric ion readily adsorbs to particulate matter, and when deposited in anoxic environments, such as lake or marine sediments, Hg²⁺ can be metabolized from there by anaerobic microbes. Microbial activity

methylates Hg, yielding *methylmercury*, CH₃Hg⁺ (Figure 21.22), and this can be further methylated to form *dimethylmercury*, Hg(CH₃)₂. Methylmercury formation is associated with the activities of sulfate-reducing and iron-reducing *Bacteria* and methanogenic *Archaea*; very few aerobes have been shown to methylate mercury. In contrast to methylmercury, the formation of dimethylmercury is likely not due to microbes but instead to abiotic processes.

Methylmercury and dimethylmercury are readily absorbed through the skin of animals and are potent neurotoxins. Dimethylmercury is an extremely toxic neurotoxin and only a few microliters of liquid is sufficient to kill a human. Symptoms are slow to develop but unstoppable as this uncharged form crosses the blood–brain barrier. In addition, CH₃Hg⁺ is soluble and thus easily concentrated in the food chain, primarily in the muscle tissues of fish, and its concentration increases with each trophic level (a process called *bio-magnification*), causing a threat to humans whose diets rely heavily on fish. Methylmercury and Hg²⁺ are about 100 times more toxic than Hg⁰, and their accumulation in the aquatic food chain is particularly acute in freshwater lakes and marine coastal waters where

Figure 21.22 Biogeochemical cycling of mercury. The major reservoirs of mercury are water and sediments. Mercury in water can be concentrated in animal tissues; it can be precipitated as HgS from sediments. The volatile forms of mercury are Hg⁰ and CH₃HgCH₃. The enlarged bacterial cell shows the enzyme system responsible for mercury methylation by sulfate-reducing bacteria. Common forms of mercury are shown in different colors. THF, tetrahydrofolate. HgcA and HgcB are proteins that function to methylate mercury.

enhanced levels of CH₃Hg⁺ have been detected in fish caught for human consumption. In addition to their neurotoxicity, mercuric compounds also cause liver and kidney damage in humans and other animals, and methylmercury is a suspected human carcinogen.

Biochemistry of Mercury Methylation

Methylation of Hg²⁺ by sulfate-reducing bacteria requires two genes, *hgcA* (encoding a methyltransferase corrinoid protein) and *hgcB*, encoding a [4Fe-4S] ferredoxin-containing protein (Figure 21.22). In the reaction sequence (Figure 21.22), a methyl group is transferred from methylated HgcA to inorganic Hg²⁺. HgcB then regenerates the reduced form of HgcA that accepts a methyl group from the coenzyme methyltetrahydrofolate (Figure 21.22). Identification of *hgcA* and *hgcB* has fueled surveys of their distribution in genomic and metagenomic sequences and has revealed that genes for mercury methylation are widely distributed in species of *Bacteria* and methanogenic *Archaea*. The discovery of mercury methylation genes paves the way for developing genetic tools for surveying environments for their potential to methylate mercury and should contribute to our understanding of the physiological significance of methylation. It also allows for the identification of environmental

variables that control the expression of mercury methylation genes and insight into the observation that mercury methylation also occurs in oxic marine surface waters.

Several other microbial transformations of mercury occur in anoxic sediments, including reactions catalyzed by sulfate-reducing bacteria (H₂S + Hg²⁺ → HgS) and methanogens (CH₃Hg⁺ → CH₄ + Hg⁰) (Figure 21.22). The solubility of mercuric sulfide (HgS) is very low, so in sulfidic sediments, most Hg exists as HgS. But upon aeration, HgS can be oxidized to Hg²⁺ and SO₄²⁻ by sulfide-oxidizing bacteria (◀ Sections 14.7 and 15.12), and the Hg²⁺ is eventually converted to CH₃Hg⁺. However, it is not the Hg in HgS that is oxidized here, but instead the *sulfide*, probably by organisms related to *Acidithiobacillus* or other sulfur-oxidizing bacteria (◀ Section 15.12).

Mercury Resistance

At sufficiently high concentrations, Hg²⁺ and CH₃Hg⁺ can be toxic to microorganisms as well as to macroorganisms. However, several gram-positive and gram-negative bacteria convert toxic forms of Hg to nontoxic or less toxic forms.

These mercury-resistant bacteria employ the enzyme *organomercury lyase* to degrade the highly toxic CH₃Hg⁺ to Hg²⁺ and methane (CH₄), and the NADPH (or NADH)-linked enzyme *mercuric reductase* to reduce Hg²⁺ to Hg⁰, which is volatile and thus mobile (Figure 21.23).

In many mercury-resistant bacteria, which are predominantly aerobes, genes encoding Hg resistance (*mer* genes) reside on plasmids or transposons (◀ Sections 6.2 and 9.11). *Mer* genes are arranged in an operon under control of the regulatory protein MerR, which can function as either a repressor or an activator of transcription (◀ Section 7.3), depending on Hg availability. In the absence of Hg²⁺, MerR functions as a *repressor* and binds to the operator region of the *mer* operon, thus preventing transcription of the structural genes, *merTPABD*. However, when Hg²⁺ is present, it forms a complex with MerR, which then binds to the *mer* operon and functions as an *activator* of transcription of *mer* structural genes (Figure 21.23).

MerP is a periplasmic mercuric ion-binding protein; it binds Hg²⁺ and transfers it to the membrane transport protein MerT, which interacts with mercuric reductase (MerA) to reduce Hg²⁺ to Hg⁰ (Figure 21.23b). Thus, Hg²⁺ is not released into the cytoplasm and the final result is the release of Hg⁰ from the cell. Mercuric ion

Figure 21.23 Mechanism of mercury transformations and resistance. (a) The *mer* operon. MerR can function as either a repressor (in the absence of Hg^{2+}) or a transcriptional activator (in the presence of Hg^{2+}). (b) Transport and reduction of Hg^{2+} and CH_3Hg^+ ; the Hg^{2+} is bound by cysteine residues in the MerP and MerT proteins. MerA is the enzyme mercuric reductase and MerB is organomercury lyase.

produced from the activity of MerB is trapped by MerT and reduced by MerA, again releasing Hg^0 (Figure 21.23b). In this way, Hg^{2+} and CH_3Hg^+ are converted to the relatively nontoxic Hg^0 , which is non-polar and exits the cell through the cytoplasmic membrane.

- How is mercury detoxified by bacteria?

21.9 Human Impacts on the Carbon and Nitrogen Cycles

Human activities have major effects on the carbon and nitrogen cycles, and these effects have significance for the health of our planet in general. The period of marked human influence on these nutrient cycles began with the Industrial Revolution in the 1800s and is informally termed the *Anthropocene*, a new geological epoch. Although the greatest human impacts have been on the release of CO_2 through the burning of fossil fuels (oil, gas, and coal) and from extensive and ongoing deforestation, human activity has also profoundly affected the nitrogen cycle. We discussed earlier the close coupling of the carbon and nitrogen cycles (Section 21.1), and here we consider some of the projected biogeochemical consequences of human alteration of these two critical nutrient cycles.

CO_2 , Other Trace Gases, and Global Warming

Atmospheric CO_2 levels have increased approximately 40% since the beginning of the Industrial Revolution and are now higher

than at any time in the last 800,000 years. In mid-2019, atmospheric levels of CO_2 reached 415 parts per million—its highest level in human history (Figure 21.24). Carbon dioxide is one of several *trace gases* (primarily water vapor, CO_2 , CH_4 , and N_2O) that comprise less than 0.5% of the atmosphere but contribute significantly to terrestrial and atmospheric warming due to the *greenhouse effect*, the ability of these gases to trap the infrared radiation emitted by Earth. Atmospheric concentrations of all of these trace gases are rapidly increasing as a consequence of human activities (Figure 21.24). The change in global warming potential resulting from the addition of these gases to the atmosphere is expressed as **radiative forcing**, defined as the difference between sunlight energy absorbed by Earth and energy radiated back to space, measured in watts per square meter of Earth's surface (W m^{-2} ; Figure 21.24d). Radiative forcing is used to calculate an Annual Greenhouse Gas Index (AGGI), defined as the ratio of the total direct radiative forcing due to long-lived greenhouse gases for a given year to that which was present in 1990 (the baseline year for the Kyoto Protocol for controlling greenhouse gas emissions).

In 2018, the AGGI was 1.43, an increase in radiative forcing of 43% since 1990. Climate models incorporate both the radiative forcing values and the atmospheric lifetimes of the major greenhouse gases. Although methane and N_2O have greater radiative forcing per unit molecule than CO_2 (58- and 206-fold, respectively), they are at much lower concentrations and therefore contribute less to warming (Figure 21.24d). CO_2 is the major contributor to the AGGI in terms of both amount and rate of increase. The atmospheric lifetime of a molecule of N_2O is around 150 years. In contrast, there is more uncertainty about the atmospheric lifetimes of methane and CO_2 , now estimated at about 10 and 120 years, respectively. The long lifetimes of N_2O and CO_2 mean that once these gases are added to the atmosphere, they will impact Earth's climate for centuries. In contrast, the much shorter lifetime of methane indicates that any reductions in emissions would have a much more immediate impact on warming.

Also shown in Figure 21.24d is radiative forcing attributed to chlorofluorocarbons (CFCs). There is no natural source of CFCs. These compounds were chemically synthesized for use as refrigerants, aerosol propellants, and cleaning solvents. Following the discovery that they were destroying stratospheric ozone, their manufacture was effectively suspended through an international agreement, the Montreal Protocol on substances that deplete the ozone layer, which entered into force on January 1, 1989. Although the levels of major CFCs now appear to be declining, their long atmospheric lifetimes mean they will remain in the atmosphere for over 100 years. Unfortunately, analyses have identified a 25% increase in CFC release originating in eastern Asia since 2012, pointing to the difficulties in enforcing international Earth-benefiting agreements.

CO_2 and Its Effects on Aquatic Microbial Ecosystems

The increase in atmospheric CO_2 concentration, measured across a global network of sampling stations (Figure 21.24a), is currently about 2 parts per million per year. This increase would be much more rapid were it not for the high solubility of CO_2 in water, which produces carbonic acid (H_2CO_3); much anthropogenic CO_2 thus dissolves in the oceans (Figures 21.1 and 21.20c). The surface waters

Figure 21.24 Past 40-year increases in greenhouse gases and associated radiative forcing. Global average values for (a) CO_2 , (b) CH_4 , (c) N_2O . Increases in CO_2 have averaged 1.4 ppm per year before 1995 and 2 ppm per year thereafter. (d) Radiative forcing from chlorofluorocarbons (CFCs) is now stable or declining as a result of the Montreal Protocol banning production of substances that deplete the ozone layer. Greenhouse gas measurements are continuously collected by the National Oceanic and Atmospheric Association on Mauna Loa, Hawaii.

of the oceans have taken up an estimated 500 billion tons of CO_2 from the atmosphere out of a total of 1300 billion tons of total anthropogenic emissions, thus modulating the greenhouse effect somewhat. The increase in average Earth air temperature, estimated to have increased 0.75°C in the twentieth century and projected to increase by anywhere from 1.1 to 6.4°C in the twenty-first century, would also have been more rapid without the heat absorption of the oceans. Since three orders of magnitude more energy is required to raise the temperature of a cubic meter of water than a cubic meter of air, it can be calculated that over 80% of the heat retained on Earth as a result of the greenhouse effect thus far has actually entered the ocean.

Although there is considerable uncertainty about the consequences of ocean warming and CO_2 consumption on Earth's biological systems, there is agreement on how these changes will affect biogeochemistry. Warmer ocean surface waters are more buoyant because of their lower density than are deeper waters. Thus, as occurs seasonally in lakes (◀ Section 20.9), the oceans will become more stratified with future global warming. Stratification tends to slow the transfer of nutrients from deeper waters that are needed to nourish phototrophic microbes at the base of the food web in surface waters. This in turn reduces ocean productivity and export of a portion of that production to the deeper ocean through sedimentation (the biological pump, Figure 21.1).

Ocean warming is also contributing to the expansion of oxygen minimum zones (OMZs), regions of naturally occurring low O_2 concentration in subsurface waters between 100 and 1000 m in depth (◀ Section 20.10). OMZs are a consequence of both the reduced solubility of O_2 in warmer water and the increasing stratification associated with surface warming, which reduces mixing of surface and subsurface waters. Animals will be excluded from the expanding OMZs in contrast to the enhancement of anaerobic microbial processes, such as denitrification and anammox, that directly influence the nitrogen cycle and production of the greenhouse gas N_2O .

Acidification of the ocean resulting from the ongoing dissolution of anthropogenic CO_2 has reduced ocean pH by 0.1 pH units since the beginning of the Industrial Revolution and may further reduce

the pH by 0.3–0.4 units by the year 2100. The ongoing reduction in carbonate (CO_3^{2-}) concentration, a consequence of increasing acidification, is expected to be detrimental to marine calcifiers (organisms synthesizing CaCO_3 shells or skeletons, Figure 21.20). Since the concentration of Ca in seawater is relatively constant, continued reduction in CO_3^{2-} will ultimately reach a point where the dissolution of existing CaCO_3 is chemically favored, ultimately releasing more dissolved CO_2 (Figure 21.20), which reduces the capacity of the oceans to absorb more atmospheric CO_2 .

Although the biological response to ocean acidification is unknown, it is likely that coral reef ecosystems, a major component of the marine biosphere (▶ Section 23.13), will cease to occur naturally on Earth if CO_2 emissions continue at their present rate (Figure 21.24a and see the chapter opener on page 729). Calcification in foraminifera (◀ Section 18.6) will likely be impaired significantly by ocean acidification, as will calcification in coccolithophores (Figure 21.20; ◀ Section 18.7). Over periods of a century or so, the invasion of anthropogenic CO_2 into the deep ocean will ultimately result in a significant reduction in the levels of CaCO_3 sequestered there, and this will likely affect the carbon cycle in major but as yet unpredictable ways.

Methane and Global Warming: Wetlands, Permafrost, and Sea Ice

Increases in atmospheric methane have contributed to about one-fifth of the increase in radiative forcing since 1750. There are many natural sources of methane as well as several sources linked to human activities (Figure 21.25). Major natural sources of methane are wetlands (including melting permafrost), ruminants, and rice cultivation. Analysis of the stable isotopic composition of new atmospheric methane (◀ Section 19.10) suggests that the uptick since 2007 is primarily fueled by emissions from tropical wetlands, the world's largest natural source of atmospheric methane (Figure 21.25). On the human side, fossil fuel and biomass burning make up nearly a quarter of all methane emissions, and the steadily increasing numbers of domesticated ruminants used as a food source constitute a major source of methane as well.

Figure 21.25 Major sources of global methane emissions. Total methane emissions are 500–600 million metric tons per year.

Ongoing planetary warming will also increase atmospheric inputs of methane by destabilizing coastal methane hydrates (Figure 21.4) and by the melting of permafrost. That is, there is *positive climate feedback* linked to methane release. As Earth warms in response to the accumulation of greenhouse gases, attention has focused on high-latitude regions where temperatures are rising twice as fast as the global average. As temperatures rise, normally frozen ground (the permafrost subsurface layer in tundra) thaws, making vast stores of organic carbon available for microbial decomposition. Accumulated over thousands of years from past plant and animal life, the pool of carbon in the permafrost zone is estimated to be 1300–1600 billion tons. This is about 50% of global soil carbon and twice as much carbon as is currently in the atmosphere.

Predicting the rate and extent of microbial conversion of permafrost organic carbon to greenhouse gases (primarily CO_2 and CH_4) is essential in developing future climate scenarios. It is estimated that 5–15% of permafrost carbon will decompose in this century, releasing primarily CO_2 at a rate unlikely to cause abrupt climate change in the near future (a portion of the methane will be oxidized to CO_2 by methanotrophs). However, thawing permafrost will impact global climate for centuries, with current models estimating that about 60% of total permafrost carbon emissions will occur past the year 2100. Predicting the end result of such releases on the habitability of Earth is impossible at this point except to say that microbial responses to continued warming will unquestionably occur and will have consequences for all life on Earth.

An additional positive climate feedback is associated with the rapid loss of summer sea ice in the Arctic Ocean, reduced by more than 11% since 1979. Instead of reflecting back most sunlight as ice does, the sea ice melt has opened a new expanse of dark open water to absorb the sun's energy. This extra energy input, and associated flux of moisture and heat to the Arctic atmosphere, is contributing to a strong local positive feedback called the *Arctic amplification*. As a result, surface temperatures in the Arctic are rising twice as fast as

at lower latitudes and should increase releases of methane from hydrates and of methane and CO_2 from permafrost accordingly. The enormous loads of organic carbon in the Arctic place a special focus on this region as an area where microbial activities will continue to surge significantly and accelerate global warming.

Anthropogenic Effects on the Nitrogen Cycle

Anthropogenic impacts on the microbial ecology of the nitrogen cycle are nearly as profound as those on the carbon cycle. The yearly industrial production of nitrogenous fertilizers through the Haber–Bosch process, which combines $\text{N}_2 + \text{H}_2$ to form NH_3 under high temperature and pressure, is now comparable to the amount of fixed nitrogen entering the biosphere through biological nitrogen fixation, a key link in the nitrogen cycle (Section 21.3). Most of the industrially produced N is used in agriculture, and a significant fraction runs off to the oceans and contributes to coastal eutrophication (◀ Section 20.10). Large amounts are also lost as gaseous nitrogen compounds (N_2 , N_2O , and NO), primarily from nitrification of NH_3 and denitrification of NO_3^- (Section 21.3). N_2O emission is now increasing at a rate of 0.2–0.3% per year (Figure 21.24c). Agriculture—including the microbial breakdown of manure and urine—contributes about 80% of N_2O emissions in the United States. Lesser amounts come from motor vehicle emissions and industrial production of fertilizers and nitrogen-based polymers.

Transport of N from industrial and agricultural centers through the atmosphere fertilizes both terrestrial and marine systems and could cause one of at least two effects. On the one hand, if deposition suppresses microbial nitrogen fixation, this would to some degree mitigate the fertilization effect. On the other hand, a greater supply of both CO_2 and iron (caused by greater deposition of dust from areas of increasing desertification, ◀ Sections 20.6 and 20.7) along with increased N depositions could enhance primary production, since iron is also often a limiting nutrient. Either way, major effects on the carbon cycle should be expected from human inputs in the nitrogen cycle.

Although changes in Earth's biosphere from human intervention in microbial nutrient cycles are a certainty, precisely what these changes will be is less clear. However, because major nutrient cycles are closely coupled (Section 21.1 and Figure 21.6), it is likely that the significant changes already in play in the carbon and nitrogen cycles will have feedback effects on other nutrient cycles as well. Collectively, these events could upset the balance and interrelationships of Earth's nutrient cycles in general—cycles driven by the activities of microbial communities keenly attuned to their environments—and have significant (and likely negative) consequences for plants, animals, and humans.

- What is the greenhouse effect, and what causes it?
- How does nitrogen fixed by human processes contribute to an imbalance of the global nitrogen cycle?
- Why are the OMZs expanding, and what are the likely impacts on nutrient cycles?

CHAPTER REVIEW

I • Carbon, Nitrogen, and Sulfur Cycles

- 21.1** The oxygen and carbon cycles are interconnected through the complementary activities of autotrophic and heterotrophic organisms. Microbial decomposition is the single largest source of CO₂ released to the atmosphere.

Q Which metabolic class of microorganisms is considered primary producers, and where are they typically found in nature?

- 21.2** Under anoxic conditions, organic matter is degraded to CH₄ and CO₂. Methane is formed primarily from acetate and the reduction of CO₂ by H₂. The H₂ and acetate are supplied by syntrophic bacteria that depend on H₂ consumption by a partner as the basis of their energetics.

Q How can organisms such as *Syntrophobacter* and *Syntrophomonas* grow when their metabolism is based on thermodynamically unfavorable reactions? How does coculture of these syntrophs with certain other bacteria allow them to grow?

- 21.3** The principal form of nitrogen on Earth is N₂, which can be used as a N source only by nitrogen-fixing bacteria. Ammonia produced by nitrogen fixation or by ammonification can be assimilated into organic matter or oxidized to NO₃⁻. Denitrification and anammox cause major losses of fixed nitrogen from the biosphere.

Q Compare the two major pathways of anaerobic microbial N₂ formation in terms of the organisms and intermediates involved as well as their relevance in the context of greenhouse gas formation.

- 21.4** Bacteria play major roles in both the oxidative and reductive sides of the sulfur cycle. Sulfur- and sulfide-oxidizing bacteria produce SO₄²⁻, whereas sulfate-reducing bacteria consume SO₄²⁻, producing H₂S. Because sulfide is toxic and reacts with various metals, SO₄²⁻ reduction is an important biogeochemical process. Dimethyl sulfide is the major organic sulfur compound of ecological significance in nature.

Q If sulfur chemolithotrophs had never evolved, would there be a problem in the microbial cycling of sulfur compounds? What impact would coastal marine eutrophication have on microbial sulfur transformations?

II • Other Nutrient Cycles

- 21.5** Iron and manganese exist naturally in two oxidation states: Fe²⁺/Fe³⁺ and Mn²⁺/Mn⁴⁺, and typically as insoluble

minerals. Bacteria reduce the oxidized metals in anoxic environments, having evolved mechanisms for exporting electrons to the insoluble electron acceptors outside the cell to carry out the anaerobic respiration.

Q Compare the systems employed by *Geobacter* and *Shewanella* for reducing metals outside the cell.

- 21.6** The reduced forms of iron and manganese can be oxidized by a wide variety of bacteria. Ferrous iron is soluble at acidic pH, but at neutral pH, Fe²⁺ and Mn²⁺ are only soluble under anoxic conditions, and thus organisms that oxidize these metals must live at anoxic–oxic interfaces.

Q Contrast the habitats of the iron-oxidizing bacteria *Acidithiobacillus* and *Gallionella*.

- 21.7** P, Ca, and Si are elements cycled by microbial activities, primarily in aquatic environments. Calcium and silicon play important roles in the biogeochemistry of the oceans as components of the exoskeletons of coccolithophores and diatoms, respectively.

Q In what ways are Ca and Si cycling in ocean waters similar, and in what ways do they differ? How do the calcium and silicon cycles couple to the carbon cycle?

III • Humans and Nutrient Cycling

- 21.8** A major toxic form of Hg in nature is CH₃Hg⁺, which can yield Hg²⁺ that is reduced by bacteria to Hg⁰. Genes conferring resistance to the toxicity of Hg, such as those that encode enzymes that can detoxify or pump out the metal, often reside on plasmids or transposons.

Q Where do Hg-resistant genes reside? How are they controlled?

- 21.9** Anthropogenic inputs of CO₂ and reactive nitrogen are impacting major nutrient cycles. Although some consequences are reasonably well understood, including expansion of oxygen minimum zones (OMZs) and impaired growth of calcareous organisms, the long-term changes to the nutrient cycles that sustain Earth's biosphere remain unclear.

Q Describe the Haber–Bosch process used to make fertilizers and the relative amounts of fixed nitrogen it produces.

APPLICATION QUESTIONS

1. Compare and contrast the carbon, sulfur, and nitrogen cycles in terms of the physiologies of the organisms that participate in each cycle. Which physiologies are part of one cycle but not another?
2. ^{14}C -labeled cellulose is added to a vial containing some anoxic freshwater lake sediments and sealed under anoxic conditions.

A few hours later, $^{14}\text{CH}_4$ appears in the vial. Discuss what has happened to yield such a result.

3. Methane and nitrous oxide are important greenhouse gases that contribute to global warming and climate change. Discuss how bacteria can help in reducing methane and nitrous oxide emissions.

CHAPTER GLOSSARY

Denitrification anaerobic respiration in which NO_3^- or NO_2^- is reduced to nitrogen gases, primarily N_2

Global warming the warming of the atmosphere and oceans attributed to anthropogenic release of greenhouse gases,

primarily CO_2 , that trap infrared radiation emitted by Earth, ultimately leading to major changes in climate

Humus dead organic matter, some of which functions as electron shuttles for the microbial reduction of metal oxides

Radiative forcing the difference between sunlight energy absorbed by Earth and energy radiated back to space

Syntrophy a process whereby two or more microorganisms cooperate to degrade a substance neither can degrade alone

MICROBIOLOGYNOW

Sending Microbes to Clean Up after Polluters

The chlorinated solvents tetrachloroethene and trichloroethene have long been used as degreasing agents, dry cleaning fluids, and chemical feedstocks. Unfortunately, their improper disposal has contributed to extensive contamination of groundwater at thousands of sites throughout the United States. Since these solvents can be widely dispersed in the subsurface, the only feasible approach to their cleanup is to deploy microbes that can degrade them in place, a process called *in situ bioremediation*.

Bioremediation of chlorinated contaminants exploits the ability of some bacteria to use these chemicals as electron acceptors through reductive dechlorination, a form of anaerobic respiration. Although dehalogenating bacteria are common, most fail to remove all of the chlorines, leaving the even more toxic and carcinogenic products dichloroethylene and vinyl chloride behind. Thus, the discovery of the bacteria *Dehalococcoides* and *Dehalogenimonas* that can completely dechlorinate these solvents and produce the benign gas ethene was critical to effective cleanup.

If these dehalogenating bacteria are naturally present, then *biostimulation* by injecting organic carbon is used to

trigger bioremediation. However, if these microbes are absent, *bioaugmentation* (the addition of microorganisms expressing a desired activity) is needed to jump-start cleanup. At a remediation site, large numbers of *Dehalococcoides* are injected along with an inexpensive carbon source such as molasses (shown here in the photo of a contaminated manufacturing site). Fermentation of the molasses by various bacteria produces the acetate and H_2 needed by *Dehalococcoides* to dehalogenate the solvents. It was initially unclear how long *Dehalococcoides* would continue to degrade solvents remaining in the groundwater after injection stopped. However, environmental microbiology research showed that these physiologically specialized microbial cleanup agents remain active for at least four years after injection is stopped, all the time continuing to protect humans from our past poor environmental stewardship.

In this chapter we address the microbiology of “built” systems. These include the infrastructure for drinking water and wastewater distribution and treatment, gas and oil transmission, building materials, private and public spaces, and environments modified for mineral extraction or for the cleanup of pollutants. By their very nature, built systems create new microbial habitats, and these promote both desired and undesired microbial activities. From the standpoint of microbial ecology, these activities are simply the natural result of microbes exploiting resources provided to them.

Microbial activity in the built environment is the proverbial double-edged sword. Examples of built systems that promote *desirable* microbial activities include biological reactors for the treatment of wastewater and the stimulation of microbial activity in aquifers to clean up environmental pollutants. By contrast, an *undesirable* activity is microbially influenced corrosion of the pipelines used for the transmission of wastewater, drinking water, and oil, activities that destroy billions of dollars’ worth of essential infrastructure yearly in the United States alone.

I • Mineral Recovery and Acid Mine Drainage

It is often remarked that microorganisms are “Earth’s greatest chemists,” and the activities of these tiny biochemical factories have been exploited in many ways. Here we consider how microbial activities help extract valuable metals from low-grade ores, and the environmental consequences thereof.

22.1 Mining with Microorganisms

One of the most common forms of iron in nature is **pyrite** (FeS_2), which is often present in coal and in metal ores. Sulfide (HS^-) also forms insoluble minerals with many metals, and many ores mined as sources of these metals are sulfide ores. If the concentration of metal in the ore is low, it may be economically feasible to mine the ore only if the desired metals are first concentrated by **microbial leaching** (Figure 22.1). The promotion of acid production and dissolution of FeS_2 by acidophilic bacteria such as *Acidithiobacillus ferrooxidans* is used to leach the metal ores in large-scale mining operations. Leaching is especially useful for copper ores because copper sulfate (CuSO_4), formed during the oxidation of copper sulfide ores, is very water-soluble. Indeed, approximately a quarter of all copper mined worldwide is obtained by microbial leaching.

The Leaching Process

The susceptibility to oxidation varies among minerals, and those minerals that are most readily oxidized are most amenable to microbial leaching. Thus, iron and copper sulfide ores such as pyrrhotite (FeS) and covellite (CuS) are readily leached, whereas lead and molybdenum ores are much less so. In microbial leaching, low-grade ore is dumped in a large pile called the *leach dump* and a dilute sulfuric acid solution at pH 2 is percolated down through the pile (Figure 22.1a). The liquid emerging from the bottom of the pile (Figure 22.1b) is rich in dissolved metals and is transported to a precipitation plant (Figure 22.1c) where the desired metal is precipitated and purified (Figure 22.1d). The liquid is then pumped back to the top of the pile and the cycle repeated. As needed, acid is added to maintain an acidic pH.

Figure 22.1 The leaching of low-grade copper ores using iron-oxidizing bacteria.

(a) A typical leaching dump. The low-grade ore has been crushed and dumped in such a way that the surface area exposed is as high as possible. Pipes distribute the acidic leach water over the surface of the pile. The acidic water slowly percolates through the pile and exits at the bottom. (b) Effluent from a copper leaching dump. The acidic water is very rich in Cu^{2+} . (c) Recovery of copper as metallic copper (Cu^0) by passage of the Cu^{2+} -rich water over metallic iron in a long flume. (d) A small pile of metallic copper removed from the flume, ready for further purification.

Figure 22.2 Arrangement of a leaching pile and reactions in the microbial leaching of copper sulfide minerals to yield metallic copper. Reaction 1 occurs both biologically and chemically. Reaction 2 is strictly chemical and is the most important reaction in copper-leaching processes. For reaction 2 to proceed, it is essential that the Fe^{2+} produced from the oxidation of sulfide in CuS to sulfate be oxidized back to Fe^{3+} by iron chemolithotrophs (see chemistry in the oxidation pond).

We illustrate microbial leaching of copper with the common copper ore CuS , in which copper exists as Cu^{2+} . *A. ferrooxidans* oxidizes the sulfide in CuS to SO_4^{2-} , releasing Cu^{2+} as shown in Figure 22.2. However, this reaction can also occur spontaneously. Indeed, the key reaction in copper leaching is actually not the bacterial oxidation of sulfide in CuS but the spontaneous oxidation of sulfide by ferric iron (Fe^{3+}) generated from the bacterial oxidation of ferrous iron (Fe^{2+}) (Figure 22.2). In any copper ore, FeS_2 is also present, and its oxidation by bacteria leads to the formation of Fe^{3+} . The spontaneous reaction of CuS with Fe^{3+} proceeds in the absence of O_2 and forms Cu^{2+} plus Fe^{2+} (Figure 22.2).

Metal Recovery

The precipitation plant is where the Cu^{2+} from the leaching solution is recovered (Figure 22.1c, d). Shredded scrap iron (a source of elemental iron, Fe^0) is added to the precipitation pond to reduce Cu^{2+} (abiotically) and recover metallic copper (Cu^0) from the leach liquid by the chemistry shown in the lower part of Figure 22.2. This produces a Fe^{2+} -rich liquid that is pumped to a shallow oxidation pond where iron-oxidizing chemolithotrophs oxidize the Fe^{2+} to Fe^{3+} . This now ferric-iron-rich acidic liquid is pumped to the top of the pile and the Fe^{3+} is used to oxidize more CuS (Figures 22.1 and 22.2). The entire CuS leaching operation is thus driven by the oxidation of Fe^{2+} to Fe^{3+} by iron-oxidizing bacteria.

Temperatures rise in a leaching dump and this leads to shifts in the iron-oxidizing microbial community. *A. ferrooxidans* is a mesophile, and when heat generated by microbial activities raises temperatures above about 30°C inside a leach dump, this bacterium is outcompeted by mildly thermophilic, iron-oxidizing chemolithotrophic *Bacteria* such as *Leptospirillum ferrooxidans* and *Sulfobacillus*. At even higher temperatures ($60\text{--}80^\circ\text{C}$), hyperthermophilic *Archaea* such as *Sulfolobus* (Section 17.10) predominate in the leach dump.

Other Microbial Leaching Processes: Uranium and Gold

Bacteria are also used in the leaching of uranium (U) and gold (Au) ores. In uranium leaching, *A. ferrooxidans* oxidizes U^{4+} to U^{6+} with O_2 as an electron acceptor. However, U leaching depends more on the abiotic oxidation of U^{4+} by Fe^{3+} with *A. ferrooxidans* contributing to the process mainly through the reoxidation of Fe^{2+} to Fe^{3+} , as in copper leaching (Figure 22.2). The reaction observed is as follows:

Unlike UO_2 , the uranyl sulfate (UO_2SO_4) formed is highly soluble and is concentrated by other processes.

Gold is typically present in nature in deposits associated with minerals containing arsenic (As) and FeS_2 . *A. ferrooxidans* and related bacteria can leach the arsenopyrite minerals, releasing the trapped Au:

The Au is then complexed with cyanide (CN^-) by traditional gold-mining methods. Unlike copper leaching, which is done in a huge dump (Figure 22.1a), gold leaching is done in small bioreactor tanks (Figure 22.3), where more than 95% of the trapped Au can be released. Moreover, the potentially toxic As and CN^- residues from the mining process are removed in the gold-leaching bioreactor. Arsenic is removed as a ferric precipitate, and CN^- is removed by its bacterial oxidation to CO_2 plus urea in later stages of the Au recovery process. Small-scale microbial-bioreactor leaching has thus become popular as an alternative to the environmentally devastating gold-mining techniques that leave a toxic trail of As and CN^- at the extraction site. Pilot processes are also being developed for bioreactor leaching of zinc, lead, and nickel ores.

Figure 22.3 Gold bioleaching. Gold leaching tanks in Ghana (Africa). Within the tanks, a mixture of *Acidithiobacillus ferrooxidans*, *Acidithiobacillus thiooxidans*, and *Leptospirillum ferrooxidans* solubilizes the pyrite/arsenic mineral containing trapped gold, which releases the gold.

We now examine the other side of the coin—environmental damage from microbial mining.

Check Your Understanding

- What is required to oxidize CuS under anaerobic conditions?
- What key role does *Acidithiobacillus ferrooxidans* play in the copper leaching process?

22.2 Acid Mine Drainage

Although microbial leaching has tremendous value in mining operations, the same process has contributed to extensive environmental destruction where mining operations improperly handle or dispose of pyrite-containing coal and mineral deposits. Bacterial and spontaneous oxidation of sulfide minerals is the major cause of **acid mine drainage**, an environmental problem worldwide caused by surface mining operations. As described for the oxidation of copper sulfides promoted in microbial mining (Section 22.1), the oxidation of FeS₂ is a combination of chemically and bacterially catalyzed reactions, and two electron acceptors participate in the process: O₂ and Fe³⁺. When FeS₂ is first exposed in a mining operation (Figure 22.4a, b), a slow chemical reaction with O₂ begins (Figure 22.4c). This reaction,

Figure 22.5 Acid mine drainage from a surface coal-mining operation. The yellowish-red color is due to the precipitated iron oxides in the drainage (see Figure 22.4c for the reactions in acid mine drainage).

called the *initiator reaction*, leads to the oxidation of HS[−] to SO₄^{2−} and the development of acidic conditions as Fe²⁺ is released. *Acidithiobacillus ferrooxidans* and *Leptospirillum ferrooxidans* then oxidize Fe²⁺ to Fe³⁺, and the Fe³⁺ formed under these acidic conditions, being soluble, reacts spontaneously with more FeS₂ and oxidizes the HS[−] to sulfuric acid (H₂SO₄), which immediately dissociates into SO₄^{2−} and H⁺:

Again, the bacteria oxidize Fe²⁺ to Fe³⁺, and this Fe³⁺ reacts with more FeS₂. Thus, there is a progressive, rapidly increasing rate at which FeS₂ is oxidized, called the *propagation cycle* (Figure 22.4c). Under natural conditions some of the Fe²⁺ generated by the bacteria leaches away and is subsequently carried by anoxic groundwater into surrounding streams. However, bacterial or spontaneous oxidation of Fe²⁺ then takes place in the aerated streams, and because O₂ is present, the insoluble Fe(OH)₃ is formed.

As we have seen (Figure 22.4c), the breakdown of FeS₂ ultimately leads to the formation of H₂SO₄ and Fe²⁺; in waters in which these products have formed, pH values can be lower than 1. Mixing of acidic mine waters into rivers (Figure 22.5) and lakes seriously degrades water quality because both the acid and the dissolved metals (iron, aluminum, and heavy metals such as cadmium and lead) are toxic to aquatic organisms.

The O₂ requirement for the oxidation of Fe²⁺ to Fe³⁺ explains how acid mine drainage develops. As long as the pyritic material is not mined, FeS₂ cannot be oxidized because O₂, water, and the bacteria cannot reach it. However, when a mineral or coal seam is exposed (Figure 22.4b), O₂ and water are introduced, making both spontaneous and bacterial oxidation of FeS₂ possible. The acid formed can then leach into surrounding aquatic systems (Figure 22.5).

Where acid mine drainage is extensive and Fe²⁺ levels high, a strongly acidophilic species of *Archaea*, *Ferroplasma*, is often present. This aerobic iron-oxidizing organism is capable of growth at pH 0 and at temperatures up to 50°C. Cells of *Ferroplasma* lack a cell wall and are phylogenetically related to *Thermoplasma*, also a cell-wall-lacking

Figure 22.4 Coal and pyrite. (a) Coal from the Black Mesa formation in northern Arizona (USA); the gold-colored spherical discs (about 1 mm in diameter) are particles of pyrite (FeS₂). (b) A coal seam in a surface coal-mining operation. Exposing the coal to oxygen and moisture stimulates the activities of iron-oxidizing bacteria growing on the pyrite in the coal. (c) Reactions in pyrite degradation. The primarily abiotic initiator reaction sets the stage for the primarily bacterial oxidation of Fe²⁺ to Fe³⁺. The Fe³⁺ attacks and oxidizes FeS₂ abiotically in the propagation cycle.

and strongly acidophilic (but chemoorganotrophic) member of the *Archaea* (◀ Section 17.3).

In Part II, we explore the use of microbes in cleaning up several undesirable agents that, one way or the other, end up in the environment.

Check Your Understanding

- In what oxidation state is iron in the mineral $\text{Fe}(\text{OH})_3$? In FeS ? How is $\text{Fe}(\text{OH})_3$ formed?
- Natural pyritic deposits, such as underground coal seams, do not contribute to acid mine drainage; why not?

II • Bioremediation

Bioremediation is the microbial cleanup of oil, toxic chemicals, or other environmental pollutants by stimulating the degradative activities of indigenous microbes or by the addition of microbes having the needed degradative capacity. These pollutants include both natural materials, such as petroleum products, and synthetic chemicals new to nature.

Bioremediation is the process by which toxic or otherwise dangerous materials are cleaned up using microbes as the cleaning agents. Major successes thus far have been registered with spills of crude oil or the leakage of hydrocarbons from bulk storage tanks because the microbiology of hydrocarbon cleanup is well founded. But many other materials can be bioremediated, including chlorinated pollutants such as solvents and pesticides, and even radioactive waste in uranium-contaminated environments, a legacy of past

mining of uranium for nuclear fuel and weapons. We begin with a consideration of this very toxic pollutant.

22.3 Bioremediation of Uranium-Contaminated Environments

Major classes of inorganic pollutants are metals and radionuclides that cannot be destroyed but only altered in chemical form. Often the extent of environmental pollution is so great that physical removal of the contaminated material is impossible. Thus, *containment* is the only real option, and a common goal in the bioremediation of inorganic pollutants is to change their mobility, making them less likely to move in groundwater and contaminate surrounding environments. The containment of uranium is a prime example.

Bioremediation of Uranium

Uranium contamination of groundwater has occurred at sites in the United States and elsewhere where uranium ores have been processed or stored (Figure 22.6), and the movement of radioactive materials offsite via groundwater is a threat to environmental and human health. Because the contamination is often widespread, making mechanical methods of recovery very expensive, microbiologists have joined forces with engineers to develop biological treatments that exploit the ability of some bacteria to reduce U^{6+} to U^{4+} . Uranium as U^{6+} is soluble, whereas U^{4+} forms an immobile uranium mineral called *uraninite* (UO_2), thus limiting the movement of U into groundwater and potential contact with humans and other animals.

Bacterial Transformations of Uranium

In order to change the oxidation state of U in major uranium contaminants to a form that will stabilize the element, *Bacteria*, including metal-reducing *Shewanella* and *Geobacter* species (◀ Section 15.13) and sulfate-reducing *Desulfovibrio* species (◀ Section 15.11), couple the oxidation of organic matter and H_2 to the reduction of U^{6+} to U^{4+} .

Field studies in which organic electron donors such as acetate have been injected into uranium-contaminated aquifers to stimulate U^{6+} reduction have shown that this can lower U levels to below the U.S. Environmental Protection Agency's drinking water standard of $0.126 \mu\text{M}$. Natural levels of organic matter are typically very low in the subsurface (◀ Section 20.8), but can be sufficient to support microbial activities including anaerobic respiration using U^{6+} as electron acceptor. However, even though uraninite is stable under reducing conditions, if conditions become oxic, it reoxidizes (primarily abiotically by manganese oxide minerals) and once again becomes mobile.

Figure 22.6 Uranium bioremediation. An experimental plot at a United States Department of Energy uranium-contaminated site. Organic carbon (acetate) is being infused into the site (see inset photo) and travels in groundwater in the direction of the arrow shown in the main photo. Acetate is an electron donor for reduction of U^{6+} to U^{4+} , which immobilizes the uranium.

Figure 22.7 Environmental consequences of large oil spills and the effect of bioremediation. (a) A contaminated beach along the coast of Alaska containing oil from the *Exxon Valdez* spill of 1989. (b) The rectangular plot (arrow) was treated with inorganic nutrients to stimulate bioremediation of spilled oil by microorganisms, whereas areas above and to the left were untreated. (c) Oil spilled into the Mediterranean Sea from the Jiyeh (Lebanon) power plant that flowed to the port of Byblos during the 2006 war in Lebanon.

Much ongoing uranium bioremediation research is focused on questions of whether microbially reduced uranium is stable if the composition of the microbial community changes or if oxidants, such as O_2 , NO_3^- , and Fe^{3+} , are introduced via groundwater. This is obviously an important question because uraninite stability must be targeted for the long term in order to account for the long half-life of nuclear decay of uranium; U^{238} , the most common isotope of uranium, has a half-life approximately equal to the age of Earth (4.5 billion years)!

Check Your Understanding

- Which reaction, oxidation or reduction, is key to uranium bioremediation?
- Why is immobilization a good strategy for dealing with uranium pollution?

22.4 Bioremediation of Organic Pollutants: Hydrocarbons

Organic pollutants, unlike inorganic pollutants, can generally be completely degraded by microorganisms, eventually to CO_2 . This is true of petroleum released in oil spills (Figure 22.7), which can be attacked by many different microorganisms. These organisms have been exposed to complex mixtures of hydrocarbons through natural or accidental oil and gas seeps (◀ Figures 20.23 and 20.24) for millennia and thus have evolved the catabolic machinery necessary to degrade this naturally occurring pollutant. In contrast, artificial pollutants (xenobiotics, see Section 22.5) tend to be more persistent and are degraded by more specialized groups of microorganisms. In this section we focus on hydrocarbons and in the next section on xenobiotics.

Petroleum and Hydrocarbon Bioremediation

Petroleum is a rich source of organic matter, and because of this, microorganisms readily attack hydrocarbons when petroleum is pumped to Earth's surface and comes into contact with air and moisture. Under some circumstances, such as in bulk petroleum storage tanks, microbial growth is undesirable. However, in oil

spills, biodegradation is desirable and can be promoted by the addition of inorganic nutrients to balance the huge influx of organic carbon from the oil (Figure 22.7b).

The biochemistry of hydrocarbon catabolism was covered in Sections 14.23 and 14.24. Both aerobic and anaerobic biodegradation is possible. We emphasized that under oxic conditions, oxygenase enzymes play an important role in introducing oxygen atoms into the hydrocarbon. Our discussion here will focus on *aerobic* processes because it is only when O_2 is present that oxygenase enzymes can function and hydrocarbon bioremediation can be effective in a relatively short time.

Diverse bacteria, fungi, and a few green algae can oxidize petroleum products aerobically. Small-scale oil pollution of aquatic and terrestrial ecosystems from human as well as natural activities is common. Oil-oxidizing microorganisms develop rapidly on oil films and slicks, and hydrocarbon oxidation is most extensive if the temperature is warm enough and supplies of inorganic nutrients (primarily N and P) are sufficient. Moreover, because oil is insoluble in water and is less dense, it floats to the surface and forms slicks. There, hydrocarbon-degrading bacteria attach to the oil droplets (Figure 22.8) and eventually decompose the oil and disperse the slick. Certain oil-degrading bacteria are specialist species. For example, the bacterium *Alcanivorax borkumensis* grows only on hydrocarbons, fatty acids, or pyruvate. This organism produces surfactant chemicals that help break up the oil and solubilize it. Once solubilized, the oil can

Figure 22.8 Hydrocarbon-oxidizing bacteria in association with oil droplets. The bacteria are concentrated in large numbers at the oil–water interface but are actually not within the droplet itself.

be incorporated more readily and catabolized as an electron donor and carbon source.

In large surface oil spills such as those shown in Figure 22.7, volatile hydrocarbons, both aliphatic and aromatic, evaporate quickly without bioremediation, leaving nonvolatile components for cleanup crews and microorganisms to tackle. Microorganisms consume oil by oxidizing it to CO_2 . When bioremediation activities are promoted by inorganic nutrient application, oil-oxidizing bacteria typically develop quickly after an oil spill (Figure 22.7b), and under ideal conditions, 80% or more of the nonvolatile oil components can be oxidized within one year. However, certain oil fractions, such as those containing branched-chain and polycyclic hydrocarbons, are not preferred microbial substrates and remain in the environment much longer. Spilled oil that finds its way into sediments is even more slowly degraded and can have a significant long-term impact on fisheries that depend on unpolluted waters for productive yields.

A notable exception to the more common surface spill of oil was the 2010 sinking of the Deepwater Horizon offshore drilling platform in the Gulf of Mexico, resulting in the rupture of the wellhead at a depth of 1.5 km and the release of over 4 million barrels (635 million liters) of oil and hydrocarbon gases into the deep ocean (◀ Section 20.10 and Figure 20.23). About 35% of the resulting hydrocarbon plume was comprised of low-molecular-weight components and natural gas (methane, ethane, propane). The availability of these more easily degraded oil components likely accelerated the natural degradation process by stimulating the development of a bloom of bacteria having the capacity to oxidize both the easily degraded and more recalcitrant hydrocarbon components. Chemical dispersants were also added directly to the oil plume to accelerate microbial degradation, and much of the oil eventually disappeared through a combination of volatilization and microbial activities.

Degradation of Stored Hydrocarbons

Interfaces where oil and water meet often form on a large scale. Besides water that separates from crude petroleum during storage and transport, moisture can condense inside bulk fuel storage tanks (Figure 22.9) where there are leaks. This water eventually accumulates in a layer beneath the petroleum. Gasoline and crude

Figure 22.9 Bulk petroleum storage tanks. Fuel tanks often support microbial growth at oil–water interfaces.

oil storage tanks are thus potential habitats for hydrocarbon-oxidizing microorganisms. If sufficient sulfate (SO_4^{2-}) is present in the oil, as is often the case with crude oils, sulfate-reducing bacteria can grow in the tanks, consuming hydrocarbons under anoxic conditions (◀ Sections 14.12, 14.24, and 15.11). The sulfide (H_2S) produced is highly corrosive and causes pitting and subsequent leakage of the tanks along with souring of the fuel. Aerobic degradation of stored fuel components is less of a problem because the storage tanks are sealed and the fuel itself contains little dissolved O_2 .

22.5 Bioremediation and Microbial Degradation of Major Chemical Pollutants: Chlorinated Organics and Plastics

Unlike hydrocarbons, many chemicals that humans put into the environment have never been there before; these are **xenobiotics**, substances not previously present on Earth and new to microbial communities.

Catabolism of Organohalogens: The Chlorinated Organics

Major chemical pollutants are primarily xenobiotics. These include pesticides, polychlorinated biphenyls (PCBs), munitions, dyes, and chlorinated solvents, among many other chemicals. Some xenobiotics differ chemically in such major ways from anything organisms have experienced in nature that they are slow to biodegrade. In these cases, human intervention is often required to promote and accelerate degradation. We focus here on microbial degradation of major chlorinated compounds that are among the most common of environmental pollutants, either through widespread targeted application, as for pesticides, or through improper disposal or manufacture of chemicals used primarily in industrial applications.

Microorganisms that degrade chlorinated compounds are widespread in nature and evolved a natural halogen cycle long before the introduction of manufactured chemicals. Some natural chlorinated compounds originate from forest fires and volcanic eruptions. Others are the products of microbial synthesis of specific bioactive compounds, including haloalkanes and secondary metabolites produced by algae, fungi, bacteria, plants, and some animals. These likely provide the producing organisms a competitive advantage over predators or competitors, but few have been fully characterized. Today, well over 5000 different natural organohalogens have been identified and some are being studied for use in clinical medicine. A notable example is a bioactive secondary metabolite produced by the marine actinobacterium *Salinispora tropica*; the metabolite, salinosporamide A (Figure 22.10), is in

Figure 22.10 Examples of xenobiotic compounds. Although none of these compounds is a natural compound (except for salinosporamide A), microorganisms exist that can break them down.

clinical development for treatment of myeloma, a cancer of white blood cells.

The microbial synthesis and degradation of naturally occurring organohalogens provides a rich natural source of enzymes for the degradation of the manufactured organohalogens that now pollute the environment. Although some organohalogens are degraded only very slowly, most function as either electron donors or terminal electron acceptors for microbial growth, and virtually all are metabolized by microorganisms.

Over 1000 pesticides have been marketed worldwide and include *herbicides*, *insecticides*, and *fungicides*. Pesticides display a wide variety

of chemistries and include chlorinated, aromatic, and nitrogen- and phosphorus-containing compounds (Figure 22.10 and see Explore the Microbial World, “Solving the Marine Methane Paradox,” in Chapter 21). Highly chlorinated compounds are typically the pesticides most resistant to microbial attack. For example, chlorinated compounds such as DDT persist relatively unaltered for years in soils, whereas compounds such as 2,4-D (Figure 22.10) are significantly degraded in just a few weeks. Environmental factors, such as temperature, pH, aeration, and organic content of the soil, influence the rate of pesticide decomposition, and some pesticides can disappear from soils nonbiologically by volatilization, leaching, or spontaneous chemical breakdown. In addition, some pesticides are degraded only when other organic material is present that can be used as the primary energy source, a phenomenon called *cometabolism*. In many cases, pesticides that are cometabolized are only partially degraded, generating new xenobiotic compounds that may be even more toxic or difficult to degrade than the original compound. Thus, from an environmental standpoint, cometabolism of a pesticide is not always a good thing.

Aerobic and Anaerobic Dechlorination

The microbial degradation of chlorinated xenobiotics (Figure 22.10) is generally initiated by *dechlorination*. In aerobes, dechlorination is most often catalyzed by halogenase enzymes having specific substrate requirements. For example, a specific monooxygenase catalyzes removal of the first chlorine from the aromatic ring of the insecticide pentachlorophenol (Figure 22.11). This is followed by reductive elimination of two additional chlorines, dioxygenase ring cleavage, and elimination of the final chlorine to generate products that enter the citric acid cycle (◀ Section 3.6). In contrast to this very specific pathway for catabolism of pentachlorophenol, oxidative degradation of trichloroethylene (TCE) and vinyl chloride is initiated by cometabolism in which a relatively nonspecific monooxygenase generates an unstable epoxide that decomposes abiotically to form harmless products (see Figure 22.12).

Although the aerobic breakdown of chlorinated xenobiotics is undoubtedly ecologically important, **reductive dechlorination** may be even more so because of the rapidity with which anoxic conditions develop in polluted microbial habitats. We previously described reductive dechlorination as a form of anaerobic respiration in which chlorinated organic compounds such as chlorobenzoate ($C_7H_4O_2Cl^-$) are terminal electron acceptors that when reduced release chloride (Cl^-), a nontoxic substance (◀ Section 14.13).

Many compounds can be reductively dechlorinated, including dichloro-, trichloro-, and tetrachloro- (perchloro-) ethylene,

Figure 22.11 Pentachlorophenol metabolism by *Spingobium chlorophenolicum*. A monooxygenase catalyzes the first chlorine removal from pentachlorophenol, followed by two reductive dehalogenase steps before the aromatic ring is cleaved by a dioxygenase. A subsequent dehalogenation reaction yields a product that can enter central metabolism.

Figure 22.12 Anaerobic and aerobic pathways for PCE and TCE degradation. Top panel: Anaerobic pathway for reductive dechlorination by *Dehalococcoides* species. Lower panel: cometabolic epoxide formation and abiotic product decay catalyzed aerobically by a monooxygenase enzyme. Monooxygenases generate unstable epoxides of both TCE and PCE.

chloroform, dichloromethane, and polychlorinated biphenyls (some of these are shown in Figure 22.10). In addition, several brominated and fluorinated organic compounds can be dehalogenated in analogous fashion. Many of these halogenated compounds are highly toxic and some have been linked to cancer (particularly trichloroethylene and vinyl chloride). Some of these compounds, such as PCBs, have been widely used as insulators in electrical transformers and enter anoxic environments from slow leakage of the transformer or from leaking storage containers. Moreover, perchloroethylene (PCE) is commonly used as a dry-cleaning solvent. Eventually these compounds end up in groundwater or sediment, where they are among the most common contaminants detected in the United States. There is therefore great interest in reductive dechlorination as a bioremediation strategy for their removal from anoxic environments, as we now consider.

Bioremediation of PCE and TCE

The organohalogen TCE and PCE are poorly soluble, but both can be degraded aerobically by monooxygenase enzymes, such as methane monooxygenase of methanotrophic bacteria (Section 14.16), to form nontoxic organic compounds (Figure 22.12). Early remediation efforts employed this activity to eliminate TCE from polluted sites. However, this is a cometabolic process that yields no energy for growth of methanotrophs, and maintaining activity required the continuous injection of both oxygen and methane—an explosive gas mixture—into the subsurface.

More successful remediation is now based on stimulating the growth of organisms capable of using organohalogenes as electron acceptors (anaerobic respiration), thus avoiding the need to inject gases into the subsurface. Many facultative or obligate anaerobes capable of organohalogen respiration are known (Figure 22.13). *Obligate* organohalide-respiring bacteria grow only by organohalide respiration, using H_2 as an electron donor, and with the exception of *Dehalobacter* are members of the *Chloroflexi* (Figure 22.13). In contrast, *facultative* organohalide-respiring bacteria are more physiologically and phylogenetically diverse (Figure 22.13), being able to use organic electron donors and common electron acceptors such as Fe^{3+} , SO_4^{2-} , and NO_3^- .

Since the biologically available energy from organohalide respiration decreases with decreasing number of chlorines on the

molecule, the much less favorable electron acceptor vinyl chloride (VC, Figure 22.12) often accumulates at polluted sites. This chemical is more toxic than its parent compounds, and remediation is successful only if conversion to the fully dechlorinated product, ethene, is achieved. Most organohalide-respiring bacteria are unable to fully dechlorinate PCE or TCE, but the bacterium *Dehalococcoides* can do this and supports a full bioremediation technology.

Successful bioremediation of PCE or TCE requires hydrogen (H_2) to stimulate the growth of *Dehalococcoides*. This is achieved by the injection of an inexpensive fermentable carbon source to the contaminated site, most

commonly molasses or emulsified vegetable oil (EVO). Fermentation of these generates H_2 and acetate used as the electron donor for dehalogenation and as a carbon source, respectively, by *Dehalococcoides*. Nutrient (nitrogen and phosphate) injection coupled with groundwater extraction and recirculation accelerates solvent degradation. *Bioaugmentation*—the injection of an active *Dehalococcoides* culture into the subsurface—also accelerates the process or provides an inoculum if a resident *Dehalococcoides* population is absent (see MicrobiologyNow on page 754).

Figure 22.13 Phylogeny of organohalide-respiring bacteria. Facultative organohalide respirers use other electron acceptors, such as nitrate, in addition to organohalides, and a greater variety of electron donors, including pyruvate, lactate, ethanol, and butyrate. Obligate organohalorespirers are restricted to H_2 as electron donor and organohalides as electron acceptors.

Figure 22.14 Oil-based and biodegradable plastics. (a) The monomeric structure of several synthetic plastics. (b) Structure of the copolymer of poly-β-hydroxybutyrate (PHB) and poly-β-hydroxyvalerate (PHV). (c) A brand of shampoo previously marketed in Germany and packaged in a bottle made of the PHB/PHV copolymer. (d) Drinking bottle made from PET, the only oil-based plastic now known to be significantly biodegraded by microorganisms. (e) Pathway of PET degradation by the bacterium *Ideonella sakaiensis* to generate monomers as a carbon and energy source.

Plastics

Plastics are classic examples of xenobiotics, and the plastics industry worldwide produces over 300 million tons of plastic per year, almost half of which are discarded rather than recycled. Plastics are polymers of various chemistries (Figure 22.14). Many plastics remain essentially unaltered for long periods in landfills, refuse dumps, and as litter in the environment. A significant amount of synthesized plastic enters the marine environment, and this is of particular environmental concern. Weathering of plastic debris in the ocean causes fragmentation into small particles called *microplastics* (◀ Section 20.4 and Figure 20.7) that marine invertebrates can ingest, possibly disrupting important marine food webs. Microplastics also clog the baleen filter used by baleen whales to harvest small marine invertebrates and fish.

Among commonly used plastics, only polyethylene terephthalate (PET) has hydrolyzable ester bonds that are susceptible to biodegradation (Figure 22.14d, e). Over 50 million tons of PET is produced yearly for plastic products such as soft drink and water bottles and polyester fabrics. Although the fungus *Fusarium* can slowly catabolize PET to release terephthalic acid, the bacterium *Ideonella sakaiensis* (Betaproteobacteria, ▶ Section 16.2) can attach to the surface of PET, express enzymes that depolymerize the plastic (Figure 22.14e), and use PET as a carbon and energy source. Two hydrolase enzymes of *I. sakaiensis* depolymerize PET: the exoenzyme PETase releases mono(2-hydroxyethyl) terephthalic acid (MHET), which is converted into terephthalic acid and glycol by the cell surface enzyme MHETase (Figure 22.14e). These substances then support growth of *I. sakaiensis*. Since PET is the most common plastic used for bottled drinking water, discovery of the metabolic capacities

of *I. sakaiensis* offers some hope that the tons of PET water bottles that have been casually disposed of into the environment in recent decades may eventually disappear through microbial action.

The persistence of plastic products in the environment has also fueled research into improved biodegradable alternatives to synthetic plastics including natural microbial polymers. Polyhydroxyalkanoates (PHAs) are a common bacterial storage polymer (▶ Section 2.7), are readily biodegraded, and have many of the desirable properties of synthetic plastics. PHAs can be biosynthesized in various chemical forms, each with its own unique physical properties (stiffness, shear and impact strength, and the like). A PHA copolymer containing equal amounts of poly-β-hydroxybutyrate and poly-β-hydroxyvalerate was marketed in

the past as a container for shampoo (Figure 22.14b, c). However, because synthetic plastics are currently less expensive than microbially synthesized plastics, plastics such as PET make up virtually the entire plastics market today.

III • Wastewater and Drinking Water Treatment

Appropriate treatment of wastewater is essential for maintaining environmental quality and for reducing the spread of waterborne diseases. Methods to purify wastewaters rely on the activities of microbial communities that reduce levels of organic carbon, fixed nitrogen, and phosphorus from the waste stream.

Water is the most important potential common source of infectious diseases because a single water source often serves large numbers of people, as, for example, in major cities. Thus, the microbiology of water, water transport systems, and treatments of both

wastewater and drinking water are of the utmost importance to public health.

Here we examine systems built for the chemical and biological treatment of water and the transmission systems used for delivering treated water to consumers. Existing water transmission and treatment systems consume about 4% of all electricity in the USA, and we consider more efficient technologies now being brought into application. We also examine the human health consequences of the microbial communities that develop within the pipes of municipal water distribution systems and premise plumbing.

22.6 Primary and Secondary Wastewater Treatment

Wastewater is domestic sewage or liquid industrial waste that cannot be discarded in untreated form into lakes or streams because of public health, economic, environmental, and aesthetic considerations. Wastewater treatment employs physical and chemical methods as well as industrial-scale use of microorganisms. Wastewater enters a treatment plant and, following treatment, the **effluent water**—treated wastewater discharged from the wastewater treatment facility—is suitable for release into surface waters such as lakes and streams or to drinking water purification facilities (Figure 22.15).

Wastewater and Sewage

Wastewater from sewage or industrial sources cannot be discarded in untreated form into lakes or streams. **Sewage** is liquid effluent contaminated with human or animal fecal materials and may contain potentially harmful chemicals as well as pathogenic microorganisms. Domestic wastewater is made up of sewage, “gray water”

(the water resulting from washing, bathing, cooking, and drinking), and wastewater from small-scale food processing in homes and restaurants. Industrial wastewater includes liquid discharged from the petrochemical, pesticide, food and dairy, plastics, pulp and paper, pharmaceutical, metallurgical, and manufacturing industries. All of these wastewaters must be treated—typically using physical, chemical, and microbiological processes—to remove or neutralize contaminants.

Industrial wastewater may contain highly toxic substances and are “pretreated” biologically or chemically to remove substances such as cyanide, heavy metals such as arsenic, lead, and mercury, and organic materials such as acrylamide and benzene. These substances are converted to less toxic forms by treatment with chemicals or microorganisms capable of neutralizing, oxidizing, precipitating, or volatilizing these wastes. The pretreated wastewater can then be released to the municipal wastewater treatment facility.

The major objective of wastewater treatment is to reduce organic and inorganic materials in wastewater to a level that no longer supports microbial growth and to eliminate other potentially toxic materials. The efficiency of treatment is expressed in terms of a reduction in the **biochemical oxygen demand (BOD)**, the relative amount of dissolved oxygen consumed by microorganisms to completely oxidize all organic and inorganic matter in a water sample (Section 20.9). High levels of organic and inorganic materials in the wastewater result in a high BOD. Typical BOD values for domestic wastewater, including sewage, are approximately 200 mg of O₂ per liter. For industrial wastewater from sources such as dairy plants, the values can be as high as 1500 mg/liter. An efficient wastewater treatment facility reduces BOD levels to less than 5 mg/liter in the final treated water.

Primary Treatment: Physical Removal Processes

Wastewater treatment is a multistep operation that relies on several different physical and biological processes (Figure 22.15). *Primary*, *secondary*, and sometimes additional (*tertiary*) treatments are employed to reduce biological and chemical contamination in the wastewater, and each higher level of treatment employs more complex technologies.

Primary wastewater treatment uses a series of grates and screens to physically remove large particulate materials (bottles and other heavy solids) from the wastewater. The effluent is allowed to settle for a few hours and the solids that settle to the bottom of the separation reservoir are typically treated in an anaerobic digester that consumes these solids and generates methane for energy recovery (see Figure 22.22b). The effluent (Figure 22.16) is drawn off for secondary treatment.

Secondary Treatment: Activated Sludge and Trickling Filters

Municipalities that provide only primary treatment discharge extremely polluted water with high BOD into adjacent waterways, and this triggers undesirable microbial growth and a reduction in water quality. Thus, secondary treatment is a necessity. **Secondary wastewater treatment** uses oxidative degradation reactions

Figure 22.15 Wastewater treatment processes. Effective water treatment plants use the primary and secondary treatment methods shown here. Water from primary treatment undergoes aerobic oxidation, while the sludge collected from screening and sedimentation, along with flocs and activated sludge from aerobic oxidation of wastewater, undergoes anaerobic digestion (Section 22.8 and Figure 22.22). Tertiary treatment, not shown, may also be used to reduce nutrient levels in waters released to the environment, reducing biochemical oxygen demand (BOD), nitrogen, and phosphorus to very low to undetectable levels.

John M. Martinko and Deborah O. Jung

Figure 22.16 Primary treatment of wastewater. Wastewater is pumped into the reservoir (left) where solids settle. As the water level rises, the water spills through the grates to successively lower levels. catalyzed by microorganisms under *oxic* conditions (Figure 22.17a, b) to treat wastewater containing relatively low levels of organic material. In general, wastewaters that originate from residential sources can be treated efficiently using only aerobic treatment. Secondary treatment exploits the tendency of bacteria to attach to particulate material and form biofilms (◀ Sections 4.9, 8.10, and 20.4), producing slimy, extracellular polymeric substances to form *activated sludge flocs*.

Activated sludge consists of a community of slime-forming aerobic bacteria, including in particular *Zoogloea ramigera* (Betaproteobacteria, ▶ Section 16.2) (Figure 22.18). Protists, small animals, filamentous bacteria, and fungi also attach to the flocs. The activated sludge is mixed, aerated, and circulated in the treatment tanks to promote oxidation of organic carbon by the bacteria (Figure 22.17a, b). The aerated effluent containing the flocs is then pumped into a holding tank or clarifier where the flocs settle. Some of the activated sludge is then returned to the aerator as inoculum for new wastewater, and the rest is commonly pumped to an anaerobic sludge digester (see Figure 22.22c). Because of the volumes of wastewater needing treatment, wastewaters normally stay in an activated sludge tank for 5–10 hours, insufficient for complete oxidation of all organic matter. However, during this time much soluble organic matter is adsorbed to the flocs and incorporated by microbial cells, reducing the BOD by up to 95% (most of the material with high BOD is now in the settled flocs). The flocs are then transferred to the anoxic sludge digester for anaerobic degradation to CO_2 and CH_4 (Figure 22.17b).

The *trickling filter* is an alternative method of aerobic secondary treatment (Figure 22.17c). A trickling filter is a bed of crushed rocks, about 2 m thick. Wastewater is sprayed on top of the rocks and slowly passes through the bed. The organic material in the wastewater adsorbs to the rocks, and microorganisms grow and form biofilms on the large, exposed rock surfaces. The complete mineralization of organic matter to CO_2 , ammonia, nitrate, sulfate, and phosphate takes place in the extensive microbial biofilm that develops on the rocks.

Following secondary treatment, whether by activated sludge or trickling filter, and assuming tertiary treatment (Section 22.7) is

not undertaken, the effluent is typically chlorinated or treated with ozone to further reduce the possibility of biological contamination. The treated effluent can then be discharged into streams or lakes.

Check Your Understanding

- What is biochemical oxygen demand (BOD), and why is its reduction important in wastewater treatment?
- How do primary and secondary wastewater treatment methods differ?
- Other than treated water, what are the final products of wastewater treatment? How might these end products be used?

22.7 Tertiary Wastewater Treatment: Further Removal of Phosphorus and Nitrogen

The combination of primary and secondary wastewater treatments removes a large amount of the BOD and some of the inorganic nutrients from wastewaters. However, additional treatment can generate effluent water of much higher quality. Such advanced wastewater treatment is called **tertiary wastewater treatment**. Typical goals of tertiary wastewater treatment include removal of additional BOD, removal of key inorganic nutrients required for microbial growth (in particular, ammonia, nitrate, nitrite, and phosphorus), and degradation of any remaining toxic materials. Tertiary treatment is the most complete method of treating sewage and is common in many European countries but has not been widely adopted in other parts of the world because it is expensive. Here we focus on the

biological removal of phosphorus and nitrogen, two key nutrients controlling microbial growth.

Biological Phosphorus Removal

Conventional secondary biological treatment removes only about 20% of phosphorus from wastewater, necessitating additional chemical or biological treatment. Chemical precipitation is the most commonly used process, removing up to 90% of the influent phosphorus. Removal is accomplished by the addition of either Fe or Al as chloride or sulfate salts. At near-neutral pH, Fe^{3+} forms insoluble ferric phosphate (FePO_4) or ferric hydroxide-phosphate complexes. These then precipitate and are removed as sludge.

The chemical precipitation process results in a toxic sludge, contributing to additional disposal problems. As an alternative, tertiary treatment that encourages the growth of phosphorus-accumulating bacteria removes up to 90% of phosphorus, a process called *enhanced biological phosphorus removal*, and does not generate a metal-rich sludge. Here the waste stream is processed by sequential passage through anaerobic and aerobic bioreactors (**Figure 22.19**). During the *anaerobic* phase, *phosphorus-accumulating organisms* (PAOs) utilize polyphosphate (a polymer of phosphate, ◀ Section 2.7) and glycogen reserves to generate ATP and reducing power to fuel the uptake and conversion of volatile fatty acids in the wastewater into another storage material, polyhydroxyalkanoate (PHA) (Figures 22.14b and 22.19a; ◀ Section 2.7). In the subsequent *aerobic* phase, PAOs oxidize the PHA for cell growth and replenish polyphosphate and glycogen reserves. The new biomass (sludge) with high polyphosphate content is then collected for phosphorus removal (Figure 22.19b).

The ability to store carbon as PHA under anaerobic conditions and later use this intracellular reserve for aerobic growth allows the PAOs to outcompete other chemoorganotrophs that can only consume carbon aerobically. Two of the principal PAOs, the appropriately named bacterium *Accumulibacter phosphatis* (*Betaproteobacteria*, ◀ Section 16.2) and species of the gram-positive bacterium *Tetrasphaera* (*Actinobacteria*, ◀ Section 16.10), have been used in the laboratory as model systems for the process of enhanced biological phosphorus removal.

Biological Nitrogen Removal: The Conventional Nitrification–Denitrification Process

The strict regulatory limitations on release of nitrogen as ammonia or nitrate/nitrite, also called *reactive nitrogen* (Nr), from wastewater treatment facilities reflects their adverse health effects on human and aquatic life and contribution to eutrophication of receiving water bodies (◀ Section 20.9). Thus, there has been increasing use of tertiary treatment to remove remaining Nr from wastewater following secondary treatment or anaerobic sludge digestion (see Figure 22.22).

Conventional (“classical”) treatment converts the Nr to its inert atmospheric form (N_2) using a combination of nitrification and denitrification (**Figure 22.20a**). Nitrification (◀ Section 14.9) is first used to convert ammonia to nitrate followed by anaerobic conversion of nitrate to N_2 (and some N_2O) by denitrification (◀ Section 14.11). In the following reactions for the conversion of 1 mole of ammonia to 0.5 mole of N_2 , organic carbon is represented by its chemical oxygen demand (COD), the mass of oxygen that is reduced by a specific

Figure 22.19 Enhanced biological phosphorus removal process. (a) Carbon and phosphate transitions during the treatment process. (b) Wastewater processing. During the passage of wastewater through the reactor system, the microbial community transitions from anaerobic to aerobic growth. In the anaerobic zone, short-chain fatty acids are taken up, intracellular glycogen is degraded, and internal stores of polyphosphate are released as extracellular orthophosphate. In the aerobic zone, the glycogen reserves are regenerated, extracellular phosphate is reassimilated as polyphosphate, and the intracellular stores of polyhydroxyalkanoates (PHAs) are metabolized. High-phosphorus sludge is harvested for disposal.

amount of organic matter; for example, a COD of 4 g reduces 4 g of O_2 (0.125 moles) to water:

(producing 15 g sludge biomass)

Although the primarily autotrophic ammonia- and nitrite-oxidizing microbes require little or no reduced carbon for growth and also generate very little biomass, a carbon source is required for the subsequent microbial reduction of nitrate to N_2 by denitrification. This may require supplementation with additional carbon for wastewaters having a low ratio of organic carbon to reactive nitrogen (C/N). Supplementation is commonly accomplished by adding a relatively inexpensive carbon source, such as methanol in low concentrations. However, because a typical treatment plant treats well over a million gallons (3.8 million liters) of wastewater a day, organic carbon addition can add significant costs, and this has fueled the development of less costly processes for advanced treatment.

Biological Nitrogen Removal: The Advanced Process of Nitritation–Denitrification

The cost of N_r removal can be reduced through advanced treatment processes that suppress the activity of nitrite-oxidizing bacteria, a

process called *nitritation* (Figure 22.20b). By stopping the oxidation of ammonia at nitrite, the carbon requirement for denitrification is reduced by ~40%, oxygen by ~25%, and biomass by ~40%.

(producing 9 g sludge biomass)

This makes nitrogen removal from low C/N wastewater less costly. The only complication to this treatment strategy is the need to suppress nitrite-oxidizing bacteria (NOB), since they generally have higher substrate utilization rates than the ammonia-oxidizing bacteria (AOB). Achieving cost-effective control of partial ammonia oxidation is therefore key to advanced nitrogen removal treatment systems.

Suppression of nitrite oxidation is achieved by adjusting growth conditions that differentially affect AOB and NOB, primarily those of pH and temperature. AOB grow faster than NOB at temperatures above room temperature, having a specific growth rate (◀ Section 4.7) approximately two times that of NOB at 35°C. For example, one widely used process relies on washing out NOB from a reactor operated at 30–40°C and a short sludge retention time (SRT) of 1–1.5 days (Figure 22.20b). The SRT can be controlled by the rate the reactor is fed wastewater or by allowing sludge to settle during a period without mixing before withdrawing the treated effluent. Control of

Figure 22.20 Alternative treatment processes for nitrogen removal from wastewater. (a) Classic denitrification process. (b) Advanced treatment process for more efficient and economical removal of nitrogen. Wastewater is first treated anaerobically to remove incoming nitrate by denitrification before being nitrified in a second reactor and recycled back to the receiving tank for full nitrogen removal. SRT, sludge retention time.

reactor pH provides another way to achieve partial nitrification, as an alkaline pH (7.5–8.5) favors the growth of AOB over NOB (Figure 22.20b).

Aerobic Granular Sludge Treatment

Aerobic granular sludge consists of microbial aggregates of average 0.5 to 3.0 mm diameter having settling velocities at least 10 times greater than the loosely structured microbial flocs in flocculent activated sludge (Figure 22.21b, c). Treatment systems are designed to select for granule formation by repeated removal of suspended floc material that does not settle rapidly. The greater microbial density in granules compared to that in flocs results in much greater nutrient removal capacity on a reactor volume basis than can be achieved using systems that produce flocculent sludge. In addition, the granular architecture provides another unique advantage relative to flocs. As was described for oxygen diffusion into soil aggregates (Section 20.3 and Figure 20.3), the rapid consumption of O_2 by aerobes near the granule surface results in the formation of an anoxic core in larger granules. Thus, both aerobic and anaerobic processes can be sustained within the same granule, providing spatially resolved niches for different functional guilds.

In a granular sludge reactor designed for simultaneous nitrogen and phosphate removal, the reactor is cycled between oxic and anoxic conditions by feeding of wastewater sequentially to the bottom of the reactor (Figure 22.21a). The ammonia-oxidizing bacteria

(AOB) and nitrite-oxidizing bacteria (NOB) localize near the granule surface (Figure 22.21d). Facultative denitrifying PAOs are enriched throughout the granule (Figure 22.21d). As was shown for the enhanced biological phosphorus removal process (Figure 22.19), during the anoxic phase, the PAOs consume intracellular reserves of glycogen and polyphosphate to release inorganic phosphate to the bulk wastewater, and at the same time synthesize and store PHAs [Figure 22.21a, T(stage)₂]. During the oxic phase the AOB and NOB work together to oxidize ammonia to NO_3^- . The PAO populations oxidize their intracellular reserves of PHA and take up phosphate from the bulk liquid (Figure 22.21a, T₃). The PAOs near the granule surface use oxygen as their electron acceptor for phosphate uptake, whereas those localized to the anoxic interior use nitrate or nitrite originating from ammonia oxidation for concurrent phosphate uptake and denitrification (Figure 22.21d). The granular sludge is then allowed to settle, some of the sludge is removed to recover phosphorus (Figure 22.21a, T₄), and the cycle is repeated.

High efficiencies for nitrogen and phosphorus removal have been shown for full-scale aerobic granular sludge facilities treating municipal wastewaters. As application of these treatment systems becomes more widespread, energy savings are significant, and the footprint of the wastewater treatment facility is reduced relative to traditional systems using flocculent activated sludge (Figure 22.17) designed to treat the same wastewater.

Check Your Understanding

- What are the advantages of enhanced biological phosphorus removal relative to traditional chemical removal of phosphorus?
- What are two important advantages of aerobic granular sludge technology relative to traditional activated sludge treatment?

22.8 Sludge Processing and Contaminants of Emerging Concern

The generation of significant microbial biomass (sludge) as a product of secondary and tertiary wastewater treatment requires costly landfill disposal. However, sludge volume can be reduced by **anaerobic treatment**, using the degradative and fermentative reactions of anaerobic microorganisms to lower disposal costs as well as generating methane that can be burned for energy recovery.

Anaerobic Sludge Treatment

As we saw in Section 21.2, under conditions of electron acceptor limitation, fermentation by a community of *Bacteria* and *Archaea* converts organic matter into methane and carbon dioxide (Figure 22.22b; Figure 21.7). This requires syntrophic processes in

Figure 22.21 Granular sludge wastewater treatment. (a) Simultaneous phosphorus removal and denitrification using granular sludge technology (Nereda® process). Stages of phosphate release and uptake by phosphorus-accumulating organisms (PAOs) are shown by treatment stages T_1 – T_4 . At anoxic stage T_2 , glycogen and polyphosphate intracellular reserves are consumed to fuel production of intracellular polyhydroxyalkanoate (PHA) and the release of phosphate. At T_3 , PHA is consumed to drive phosphate uptake and synthesis of intracellular polyphosphate, using O_2 or nitrite/nitrate generated by nitrification to fuel PAO denitrification. (b) The very rapid settling of granular sludge (left) relative to activated sludge (right) after only a few minutes. (c) Granules average 1–3 mm in diameter. (d) Schematic shows how the layered structure of a granule separates aerobic and anaerobic processes in the same granule.

which the fermentative organisms supply electron donors (such as H_2 and acetate) for methanogens. The treatment of wastewater sludge is an ideal example of these cooperative processes in action.

The anaerobic degradation process takes place in large, enclosed tanks called *sludge digesters* or *bioreactors* (Figure 22.22a, c). The process requires the collective activities of many different microbes, and the major reactions are summarized in Figure 22.22b. Anaerobes use polysaccharidases, proteases, and lipases to digest suspended solids and large macromolecules into soluble components. These are then fermented to yield a mixture of fatty acids, H_2 , and CO_2 ; the fatty acids are further fermented by the cooperative actions of syntrophic bacteria (◀ Sections 14.22 and 21.2) to produce acetate, CO_2 , and H_2 . These products are then converted to CH_4 , and the CH_4 is either burned off or used as fuel to heat and power the wastewater treatment plant.

Although sludge volume is greatly reduced by anaerobic treatment, significant nitrogen and phosphate remains in the liquid phase, generating a *side stream* of N- and P-rich brine, with N concentrations up to 100-fold greater than that produced by secondary treatment. The N-rich side stream must be further treated, using either conventional tertiary treatment or the anammox process, which we consider now.

Nitrogen Removal by Partial Nitrification–Anammox

Since anammox bacteria are anaerobic chemolithotrophic autotrophs (◀ Section 14.10), they do not depend on organic carbon as an electron donor or oxygen as an electron acceptor. The anammox process is as follows:

The key to using the anammox process for nitrogen removal is an initial oxidation of *only half* the ammonia in the side stream brine to nitrite, yielding a 50:50 mixture of ammonia and nitrite. This process is called *partial nitrification* (Figure 22.22d). The effluent of the partial nitrification reactor is then fed to an anammox reactor for conversion of ammonia and nitrite to N_2 . The partial nitrification reactor exploits the higher growth rate of AOB compared to NOB at the higher temperatures used, and the higher affinity of AOB for oxygen compared to NOB. By keeping reactor temperature warm and oxygen concentration low, ammonia is oxidized to nitrite at a short SRT. Since AOB and NOB are unable to grow in the absence of oxygen, anammox is the only significant process in the anoxic reactor (Figure 22.22d).

Figure 22.22 Sludge processing. (a) Anaerobic sludge digester. Only the top of the tank is shown; the remainder is underground. (b) Major microbial processes in anaerobic sludge digestion. (c) Inner workings of a sludge digester. Methane (CH_4) and carbon dioxide (CO_2) are the major products of anaerobic biodegradation. (d) Following separation of solids and liquids, the warm ammonia-rich brine (about 50% each of NH_4^+ and NO_2^-) is treated by the anammox process.

This overall process is called *partial nitrification–anammox* (PNA). Compared with conventional biological nitrogen removal (Figure 22.20a), PNA has no requirement for added organic carbon, uses less electricity, generates less sludge, and has lower emissions of greenhouse gases (primarily CO_2 and N_2O). Thus, this process greatly reduces the environmental and energy costs of more conventional nitrogen removal technology.

Contaminants of Emerging Concern

A wide variety of chemicals end up in wastewaters besides the usual organic carbon and inorganic nutrients that processing systems are designed to deal with. These include heavily used agricultural products and chemicals that demonstrate acute toxicity or carcinogenicity. However, bioactive pollutants also enter wastewater streams and pose new challenges for microbial bioremediation. These include pharmaceuticals, active ingredients in personal care products, fragrances, household products, sunscreens, prescription and other medications, and many other uncommon or xenobiotic molecules.

Unlike pesticides, these pollutants are more or less continuously discharged into the environment through the release of treated sewage, which means they do not need to persist to have environmental effects. For example, it is known that low levels of synthetic estrogen compounds, excreted in the urine of women taking birth control pills and eventually discharged in active form from wastewater treatment plants, can activate estrogen response genes in aquatic animals such as fish and contribute to the feminization of males.

The environmental threat from these emerging contaminants has created a need for newly designed wastewater treatment facilities to stimulate bioremediation of these wastes. However, because these substances are often present in very low concentrations and in some cases may be new classes of xenobiotics, they may not actually support microbial growth but rather only be degraded by cometabolism (Section 22.5) or by highly specialized species. Moreover, because wastewaters contain such high concentrations of readily degradable organic materials, structurally complex emerging contaminants may be ignored by microbes until the COD of the wastewater is greatly reduced. We can therefore expect that the bioremediation of emerging contaminants will be an active area of microbiological research in coming years.

Check Your Understanding

- What are the advantages of further treating activated sludge by anaerobic digestion?
- Why is the incomplete oxidation of ammonia essential for effective treatment of sludge brine using the anammox process?
- What advantages does the anammox process have over classical wastewater treatments for nitrogen removal?
- Give an example of an “emerging” contaminant.

22.9 Drinking Water Purification and Stabilization

Wastewater treated by secondary methods can usually be discharged into rivers and streams. However, such water is not **potable** (safe for human consumption). The production of potable water requires further treatment to remove potential pathogens, eliminate taste and odor, reduce nuisance metals such as iron and manganese, and decrease **turbidity**, which is a measure of suspended solids. **Suspended solids** are small particles of solid pollutants that resist separation by ordinary physical means.

In 1900, water purification in the United States was limited to filtration to reduce turbidity. Although filtration significantly decreased the microbial load of water, many microbes still passed through the filters and thus cases of waterborne diseases such as cholera and typhoid (► Section 33.3 and Figure 30.7) were common. Not until the practice of **chlorination** became widespread were waterborne diseases controlled. Indeed, major improvements in public health in the United States and other developed countries were largely due to the adoption of water filtration and disinfection treatment procedures. Today, waterborne diseases still occur, but are rarely linked to well-run and properly maintained municipal water facilities.

Physical and Chemical Purification

A typical municipal installation for drinking water treatment is shown in Figure 22.23a. Figure 22.23b shows the process that purifies **raw water** (also called **untreated water**) that flows through the treatment plant. Raw water is first pumped from the source, in this case a river, to a sedimentation basin where anionic polymers, alum (aluminum sulfate), and chlorine are added. **Sediment**, including soil, sand, mineral particles, and other large particles, settles out. The sediment-free water is then pumped to a **clarifier** or coagulation basin, which is a large holding tank where **coagulation** takes place.

The alum and anionic polymers form large particles from the much smaller suspended solids. After mixing, the particles continue to interact, forming large, aggregated masses, a process called **flocculation**. The large, aggregated particles (flocs) settle out by gravity, trapping microorganisms and adsorbing suspended organic matter and sediment.

After coagulation, flocculation, and sedimentation, the clarified water undergoes **filtration** through a series of filters designed to remove organic and inorganic solutes, as well as remaining suspended particles and microorganisms. The filters typically consist of thick layers of sand, activated charcoal, and ion exchangers. After this step and the previous purification steps, the filtered water is free of particulate matter, most organic and inorganic chemicals, and nearly all microorganisms.

Disinfection

Clarified, filtered water must be disinfected before it is released to the supply system as potable **finished water**. **Primary disinfection** is the introduction of sufficient disinfectant into clarified, filtered water to kill existing microorganisms and inhibit further microbial growth. Chlorination is the most common method of primary disinfection. In sufficient doses, chlorine kills most microorganisms within 30 minutes by physically oxidizing and otherwise destroying the cell and its contents. A few pathogenic protists such as *Cryptosporidium*, however, are not easily killed by chlorine treatment (► Section 34.4). In addition to killing microorganisms, chlorine oxidizes and effectively neutralizes many organic compounds. Since most taste- and odor-producing chemicals are organic compounds, chlorination thus improves water taste and smell as well as disinfecting.

Chlorine is added to water from either a concentrated solution of sodium or calcium hypochlorite or as chlorine gas from pressurized tanks. Chlorine gas (Cl_2) is commonly used in large water treatment plants because it is most amenable to automatic control.

(b)

Figure 22.23 Water purification plant. (a) Aerial view of a drinking water treatment plant in Louisville, Kentucky, USA; source water is from the Ohio River. The arrows indicate direction of flow of water through the plant. (b) Schematic overview of a typical community water purification system.

When dissolved in water, chlorine gas forms hypochlorous acid (HOCl), which dissipates within hours from treated water. To maintain adequate levels of chlorine for primary disinfection, many municipal water treatment plants introduce ammonia gas with the chlorine to stabilize the chlorine by forming **chloramine** (NH₂Cl): $\text{HOCl} + \text{NH}_3 \rightarrow \text{NH}_2\text{Cl} + \text{H}_2\text{O}$.

Chlorine is consumed when it reacts with organic materials. Therefore, sufficient quantities of chlorine must be added to finished water containing organic materials so that a small amount, called the *chlorine residual*, remains. The water plant operator performs chlorine analyses on the treated water to determine the level of chlorine to be added for **secondary disinfection**, the maintenance of sufficient chlorine residual in the water distribution system to inhibit microbial growth. A chlorine residual level of 0.2–0.6 mg/liter is the level achieved in most water supplies. After chlorine treatment, the now potable water is pumped to storage tanks from which it flows by gravity or pumps through a distribution system of storage tanks and supply lines to the consumer. Although residual chlorine inhibits growth of bacteria in the finished water prior to the water reaching the consumer, it does not protect against catastrophic system failures, such as a broken pipe in the distribution system.

Ultraviolet (UV) radiation is also used as an effective means of disinfection. As we discussed in Section 4.18, UV radiation is used to treat secondarily treated effluent from water treatment plants. In Europe, UV irradiation is commonly used for drinking water applications, and it is increasingly used in the United States. For disinfection, UV light is generated from mercury vapor lamps. Their major energy output is near 260 nm, a wavelength that is strongly absorbed by DNA and is mutagenic (◀ Section 9.4) and thus bactericidal; irradiation may also kill cysts and oocysts of protists such as *Giardia* and *Cryptosporidium*, important eukaryotic pathogens in water (▶ Section 34.4). Viruses, however, are more resistant.

UV radiation has several advantages over chemical disinfection procedures like chlorination. First, UV irradiation is a physical process that introduces no chemicals into the water. Second, UV radiation-generating equipment can be used in existing flow systems. Third, no disinfection byproducts (such as chloroform, a possible human carcinogen) are formed with UV disinfection. Especially in smaller systems where finished water is not pumped long distances or held for long periods (reducing the need for residual chlorine), UV disinfection may be preferable to reduce dependence on chlorination.

Check Your Understanding

- What specific purposes do sedimentation, coagulation, filtration, and disinfection accomplish in the drinking water treatment process?
- What general procedures are used to reduce microbial numbers in water supplies?
- What are the advantages of disinfection with ultraviolet radiation versus, or as a complement to, chemical disinfection with chlorine?

Figure 22.24 Drinking water distribution system. A municipal distribution system includes a surface reservoir, water purification plant, distribution mains, and domestic lines that encompass many miles of pipes in a typical community.

taste and odor problems that may be present in the source water, the long transit and residence times may also contribute to undesirable taste, odors, and color from biological and chemical processes. Although undesirable, taste and odor alone usually do not signal a health threat. However, water distribution systems may also promote the growth of obligate or opportunistic pathogens (▶ Section 25.4), sequester and protect pathogens, or select for more pathogenic and resistant forms of microorganisms. Even though drinking-water-associated disease often goes unreported, disease outbreaks do occur and are occasionally fatal (Chapter 33).

The Microbiology of Municipal Water Distribution Systems

Microbial growth in drinking water distribution systems can be eliminated only through complete nutrient removal (elimination of growth substrates originating from the source water and from distribution system structural materials) or by maintaining appropriate residual chlorine levels throughout the distribution system. Neither of these is realistically attainable. Growth is unavoidable as a consequence of reduction in chlorine concentration with increasing distance from the point of production together with the tendency for microorganisms to form biofilms on the pipe walls. Microorganisms

22.10 Water Distribution Systems

Once drinking water leaves the treatment facility, the water often travels long distances through municipal and premise distribution pipes from the facility to the consumer (Figure 22.24). In addition to

in biofilms are more resistant to disinfection (◀ Sections 4.9, 8.10, and 20.4), and significant microbial accumulation is found in all distribution systems, over 90% of which is in the form of biofilms that coat the pipe walls.

Culture-independent molecular techniques, in particular 16S rRNA sequence analysis (◀ Section 19.6), have been used to explore biofilms in water distribution pipes. Although these studies are showing that pathogenic species are rare, some opportunistic pathogens (▶ Section 25.4) are present and can infect susceptible humans, including infants, the elderly, and individuals with compromised immune systems. Opportunistic pathogens found in water distribution systems include (1) nontuberculous mycobacteria (including *Mycobacterium avium*, *M. intracellulare*, *M. kansasii*, and *M. fortuitum*) associated with many thousands of clinical cases each year in the United States; (2) *Legionella pneumophila* (the causative agent of Legionnaires' disease, ▶ Section 33.4); (3) *Pseudomonas aeruginosa* (which can infect the eyes, ears, skin, and lungs); and (4) opportunistic protozoan pathogens such as *Naegleria* and *Acanthamoeba* (▶ Section 34.3) that can cause keratitis and encephalitis.

Water distribution systems also support numerous grazing protists that subsist by consuming bacteria. Bacteria that survive and replicate following ingestion by these protists are potentially also less susceptible to clearance by the mammalian immune system. An example is *Legionella*, which is able to establish residence and replicate in protists inhabiting water-handling systems (Figure 22.25), including premise plumbing, shower heads, and air conditioning systems. The basic mechanisms *Legionella* uses to gain entry and replicate in a broad variety of protists (including *Acanthamoeba*, *Hartmannella*, *Naegleria*, and *Tetrahymena*) also allow it to more easily infect human cells.

In addition to *Legionella*, opportunistic pathogens that can survive or grow within protists include *Pseudomonas* and *Mycobacterium* species. Nontuberculous mycobacteria (*M. avium*, *M. intracellulare*, *M. kansasii*, and *M. fortuitum*), also called “environmental mycobacteria,” cause a variety of lung infections distinct from that of tuberculosis. These bacteria are more resistant to chlorine disinfection

and protozoal grazing and have been found to be enriched in showerheads receiving municipal water that still maintains a chlorine residual. It is possible that aerosols generated in the showering process could transmit these pathogens to humans. Thus, although water purification has made great strides in eliminating waterborne infections on a grand scale, the architecture of water distribution systems coupled with the aging condition of many systems can still compromise human health (see Figure 22.26a).

We transition now to the final part of this chapter where we examine the microbiology and microbial activities that occur in buildings, homes, and other structures.

- How could your household water system transmit disease?

IV • Indoor Microbiology and Microbially Influenced Corrosion

Indoor air, both in private dwellings and public places, as well as surfaces in the structures themselves, can be teeming with microbes. In addition, costly losses occur yearly from corrosion catalyzed by microbial activities on metal, stone, and concrete infrastructure.

Although one might think that being indoors protects a person from the microbial world, nothing could be farther from the truth. Microbes are everywhere life can be found. Moreover, microbial metabolism accelerates corrosion through the changes in pH or redox that accompany the metabolism, production of corrosive metabolites, and creation of corrosive microenvironments in biofilms. Here we examine the microbial ecosystems of the built environment and a few cases in which the microbial contribution to corrosion is well understood. Recall that we have previously seen how surfaces are favorable microbial habitats (◀ Section 20.4); virtually any surface that provides nutrients will be colonized by microorganisms.

22.11 The Microbiology of Homes and Public Spaces

Humans in urban environments spend the majority of their life indoors. They share this indoor environment with a microbiota that inhabit the air, dust, surfaces, and ventilation and water systems (Figure 22.26). The health effects of indoor microbial exposure may be positive or negative (Figure 22.26a). Pathogens, such as antibiotic-resistant *Staphylococcus aureus* and other *Staphylococcus* species, may be elevated in the indoor environment as a consequence of shedding from human skin. In contrast, the increased incidence of allergies and autoimmune disorders in children in developed countries has been attributed in part to the “too-clean” indoor environments that

CDC/Don Howard

Figure 22.26 Sources of airborne and surface-associated microorganisms in the built environment. (a) Sources of microorganisms in a typical household, including surfaces, humans, pets, plumbing systems, and outdoor air. The colors correspond to microorganisms or spores that may be beneficial or not harmful (green) or potentially detrimental (red) to human health. (b) Air particle collector (arrow) deployed in the New York City subway system for surveying the diversity of airborne bacteria by 16S rRNA gene sequencing.

reduce exposure to microbes important for “training” the immune system early in life. Thus, a microbially depleted indoor environment may actually be detrimental to human health.

In addition to living with microbes in our home environment, what microbial exposures does a person experience in major public spaces, such as subway systems, the supermarket, or even the classroom? These questions can now be addressed using 16S (or 18S) rRNA gene sequencing of DNA isolated from samples collected from different parts of the indoor environment (Figure 22.26b; ◀ Section 19.6).

Microbiology of the Indoor Air in Private Dwellings

Studies of the microbiology of indoor air and surfaces have become increasingly popular. For example, dust collected from upper trims of inside and outside doors of over a thousand homes in the United States revealed distinct indoor and outdoor microbial communities composed of fungi and bacteria. The outdoor fungi closely resemble the outdoor fungal populations found in the same geographical region, whereas the indoor bacterial communities more strongly reflect the type and number of occupants, including pets. Local geography also influences the indoor microbiome. For example, rural and farmland households harbor a greater abundance of microorganisms associated with the guts of farm animals, including the opportunistic pathogens *Bartonella*, *Enterococcus*, and *Ruminococcus*, than do urban dwellings.

In general, the overall indoor diversity of bacteria and fungi is greater than that found outdoors, reflecting a mixing of indoor and outdoor sources. A small number of fungal species are more abundant inside the house, including common molds such as *Aspergillus*, *Penicillium*, *Alternaria*, and *Fusarium*. In addition, the incidence of these fungal populations increases with the age of the dwelling and whether or not a basement is present (basements are often damp, which increases mold abundance).

Bacteria that are characteristic of the human skin (gram-positive bacteria such as *Staphylococcus*, *Streptococcus*, *Corynebacterium*, and *Propionibacterium*), feces (*Bacteroides*, *Faecalibacterium*, *Ruminococcus*),

or the vagina (*Lactobacillus*, *Bifidobacterium*, *Lactococcus*) are much more commonly found inside a house than outdoors. The increased incidence of species of the bacteria *Prevotella*, *Porphyromonas*, *Moraxella*, and *Bacteroides* is typically associated with the presence of domestic animals—in particular dogs or cats—in a home. In fact, it is possible to predict with near certainty whether a home has these pets based only on a molecular analysis of household microbiota.

In addition to the surveys of dust described above, molecular surveys of home surfaces show that the microbial communities of human hands, noses, and feet (◀ Section 10.10 and Figure 10.28; ▶ Section 24.5) closely resemble the organisms found on household surfaces, including floors, light switches, countertops, and door knobs (Figure 22.26a). Moreover, the surface-associated microbiota of a home is highly predictive of a specific family, and the composition of the microbial community has been found to shift within days of a change in home occupants.

Diagnostic microbial populations in an individual are also highly correlated with the objects they touch, such as desks, computers, phones, and chairs. For example, in a study that combined 16S rRNA gene sequencing and metabolomics (◀ Sections 10.10 and 19.8) of the surfaces of commonly touched objects, residues from medicines and personal care products such as shampoos, deodorants, and lotions were detected. The presence or absence of theophylline, a by-product of caffeine, identified coffee drinkers or nondrinkers. When information of microbial species composition and chemical profiles were combined, all the individuals working in the same office could be linked to specific office furniture and equipment at high confidence. Studies such as this point to the likely development in the not-too-distant future of microbiology-based forensics.

The common use of antimicrobials in cleansers and soaps is now known to significantly alter the indoor microbiome. Although now banned in the United States, the chlorinated antimicrobials triclosan and triclocarban were widely used and can still be found in older

household products such as soaps, cosmetics, deodorants, and kitchen cutting boards. Because gram-positive bacteria are less susceptible to these substances than gram-negative bacteria, gram-positives, including some drug-resistant species, become predictably enriched in households using these products. Thus, practices once thought to be a measure of a healthy household and good personal hygiene may actually select for, rather than eliminate, potentially harmful organisms.

Microbiology of Public Places

Public buildings, office spaces, and transit systems are another important component of the built environment. The heavily trafficked New York City municipal subway system (Figure 22.26b) alone moves over 1.5 billion passengers a year. Similar to homes, subways and offices contain a mixture of airborne microorganisms sourced from humans and the outdoor air. Because air exchange in a subway system must be extensive, most airborne microorganisms in subway systems are typical of those found outdoors. In addition, however, about 5% of the microbial population in subway air is composed of microbes that normally reside on the feet, hands, arms, and heads of humans; these are most likely shed from the more exposed areas of subway riders.

Indoor plumbing of public and private buildings is another well-recognized point of microbial exposure. Each flush of a toilet generates over 100,000 small ($<5\text{-}\mu\text{m}$) aerosol particles. Since aerosolized bacteria and viruses can remain viable for hours after they deposit on bathroom surfaces, flushing is a potential mechanism of enteric pathogen transmission as well as a means of transmitting harmless saprophytes from person to person. Transmission of human diseases caused by direct contact (such as sexually transmitted diseases) is not a major issue with bathroom fixtures because pathogens such as *Neisseria gonorrhoeae* (gonorrhea) and *Treponema pallidum* (syphilis) are very sensitive to drying. However, because of the enormous numbers of bacteria shed in feces, transmission of enteric bacteria by bathroom aerosols is a distinct possibility.

Studies of indoor microbiology continue to reveal the types and origins of microorganisms we spend much of our day in contact with, providing information that has several applications. Besides identifying potential hot spots of infectious disease, knowledge of indoor microbiology can inform the design of future construction such that new dwellings enhance beneficial exposures and limit detrimental exposures to microorganisms. Although microbe-free dwellings are impossible because humans and pets carry microbes, controlling the microbial content of recirculated air transmitted through dwellings and the development of environmentally friendly yet still effective antimicrobials for indoor use are worthwhile goals.

Check Your Understanding

- How can a microbial inventory reveal information about the presence or absence of household pets?
- Which room(s) in a private dwelling are potentially the most dangerous from a microbiology perspective, and why?
- How might microbiology be used to develop a new type of forensic science?

22.12 Microbially Influenced Corrosion of Metals

Iron is the most commonly used metal in the built environment. Water, gas, and oil distribution pipelines—especially those laid decades ago—are made of metal, and their corrosion contributes to the greatest loss of infrastructure in the built environment. Corrosion of iron by oxygen in air is thought to be solely an electrochemical process. However, much critical iron-containing infrastructure is buried or submerged, restricting exposure to oxygen, and these are subject to microbial attack. At near-neutral pH and anoxic conditions, corrosion of iron and steel is significantly accelerated by **microbially influenced corrosion (MIC)**. Microbial groups implicated in MIC include sulfate-reducing bacteria (◀ Sections 14.12 and 15.11), ferric-iron-reducing bacteria (◀ Sections 15.13 and 21.5), ferrous-iron-oxidizing bacteria (◀ Sections 14.8, 15.14, and 21.6), and methanogens (◀ Sections 14.15, 17.2, and 21.2).

Metal Corrosion by Sulfate-Reducing Bacteria

Metal structures submerged in the marine environment and pipelines used for transmission of low-grade oil are particularly subject to MIC through the activities of sulfate-reducing bacteria. Corrosion by sulfate-reducing bacteria is partly attributable to the chemically corrosive nature of hydrogen sulfide (H_2S), the product of their metabolism. Crude oils containing more than about 0.5% sulfur by weight are called “sour” and may be naturally corrosive because of the H_2S that is present. In oil fields near the ocean, such as in the Middle East and Alaska, seawater is injected to maintain reservoir pressure and force oil into the producing well. Since seawater contains nearly 30 mM sulfate, an undesirable consequence of injection is further souring by stimulating the growth of sulfate-reducing bacteria, some species of which can oxidize hydrocarbons anaerobically using sulfate as electron acceptor (Section 22.4; ▶ Section 14.24).

A strategy now used by the petroleum industry to control souring is the addition of nitrate (NO_3^-) in the injection water, stimulating the growth of nitrate-reducing bacteria. Since nitrate respiration is energetically more favorable than sulfate respiration (▶ Sections 14.11 and 14.12), the nitrate reducers outcompete sulfate reducers for usable organic electron donors in the oil. Nitrate also stimulates the growth of sulfide-oxidizing, nitrate-reducing chemolithotrophs (▶ Sections 14.7 and 15.12), thereby reversing souring by oxidizing the sulfide.

Mechanisms of Metal Corrosion

At least two mechanisms have been proposed for how sulfate reducers corrode iron. In the first mechanism, H_2 consumption by the sulfate reducer accelerates electrochemical pitting of the iron surface (Figure 22.27a). This model is based on the capacity of many sulfate reducers to use hydrogen (H_2) as an electron donor, thereby accelerating the energetically favorable but kinetically slow H_2 production originating from the chemical oxidation of elemental iron ($\text{Fe}^0 + 2\text{H}^+ \rightarrow \text{Fe}^{2+} + \text{H}_2$). The overall stoichiometry of this reaction shows that Fe^{2+} formed from pitting reacts with sulfide from sulfate reduction in an energetically favorable reaction.

A second mechanism, such as that carried out by the bacterium *Desulfopila corrodens*, has the capacity to take up electrons directly from Fe^0 (Figure 22.27b). In this mechanism, cells attached to the metal

Figure 22.27 Corrosion of iron by sulfate-reducing bacteria. Two models for the activities of sulfate-reducing bacteria in metal corrosion. (a) Oxidation of metallic iron is accelerated by bacterial consumption of H_2 produced abiotically by proton reduction at the metal surface. (b) Direct electron transfer from the metal occurs via electron-conductive outer cell wall structures connecting to an electron transfer system spanning the periplasm. (c) Top: photo of a model iron surface undergoing sulfidic corrosion. Bottom: scan of a side view of the metal surface in the photo shows in dark green the areas where corrosion and pitting of the metal surface is greatest.

surface engage in direct (cathodic) electron uptake from Fe^0 through an electroconductive sulfidic corrosion layer (Figure 22.27b), likely facilitated by conductive cellular structures like those used in the oxidation or reduction of insoluble electron donors or acceptors (◀ Sections 15.13 and 21.5). A similar ability to take up electrons directly from Fe^0 has been observed for a *Methanobacterium* species that produces methane (CH_4) from CO_2 reduction rather than sulfide from sulfate reduction during growth on Fe^0 . The Fe^{2+} resulting from methanogenic Fe^0 oxidation then complexes with HCO_3^- to form FeCO_3 (Figure 22.27b). However, regardless of mechanism and the organism oxidizing the Fe^0 , the end result is metal corrosion (Figure 22.27c).

Check Your Understanding

- How does a nitrate addition prevent sulfide souring of crude oil?
- Why is accelerated microbial corrosion of iron metal thought to require a direct interaction between the sulfate reducers and the metal surface?

22.13 Biodeterioration of Stone and Concrete

In the same way that microorganisms contribute to soil formation through the dissolution of mineral and rock surfaces by their physical and metabolic activities (◀ Section 20.6), buildings or other structures composed of natural stone or concrete are also subject to microbial colonization and may undergo a slow loss of structural integrity through microbial metabolic activities. This degradative process is called **biodeterioration**.

Biodeterioration of Stone Building Materials

Microbial colonization of natural and structural stone building material is ubiquitous. Microbes can colonize the surface and penetrate several millimeters into rocky material depending on its physical characteristics (e.g., surface roughness, porosity, light penetration). Microbes can also grow on and within the facades of buildings constructed of limestone, sandstone, granite, basalt, and soapstone. These “within stone,” or *endolithic*, communities are phylogenetically

diverse, comprised of chemoorganotrophic and chemolithotrophic *Bacteria* and *Archaea*, microbial eukaryotes including fungi and algae, and cyanobacteria (◀ Figure 18.35). The cyanobacteria and algae primarily nourish the community, living in close or symbiotic association with other microbial members.

Life on and within stone building materials requires adaptation to multiple extreme conditions, including intense solar radiation, desiccation, temperature and moisture fluctuations, and lack of nutrients. Protection from solar radiation is conferred by production of UV-absorbing pigments (for example, melanin, mycosporines, and carotenoids) by fungi and other microbial community members. The fungi also play a central role in this process of slow biodegradation through the production of oxalic acid, which dissolves and mobilizes mineral constituents of the stone. Mineral dissolution and mobilization provide the communities with nutrients and increase habitability by enlarging pore spaces within the stone and thereby accelerating deterioration.

Crown Corrosion of Wastewater Distribution Systems

A rapid form of microbial biodeterioration is observed in the **crown corrosion** of concrete sewer tiles, a process leading ultimately to collapse of the pipe. Crown corrosion is a consequence of interactions between sulfate-reducing bacteria (◀ Sections 14.12 and 15.11) and chemolithotrophic sulfur-oxidizing bacteria (◀ Sections 14.7 and 15.12) in these underground wastewater transmission systems (Figure 22.28).

The first step in crown corrosion is the reduction of sulfate in the sewage to H_2S by sulfate reducers, using primarily organic electron donors available in the waste stream water. The H_2S is then released into the headspace of the pipe where conditions are oxic. The sulfide, or partially oxidized intermediates such as thiosulfate or sulfur, is then oxidized by neutrophilic thiobacilli such as *Thiobacillus thioautotrophicus*. As the pH drops to 4–5 with continued microbial production of sulfuric acid, acidophilic sulfur-oxidizing species such as *Acidithiobacillus thiooxidans* displace the neutrophilic species. Destruction and ultimate structural failure of the concrete results from the reaction of sulfuric acid with lime in the concrete, producing $\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$ (gypsum) that penetrates into the concrete. The gypsum subsequently reacts

Figure 22.28 Crown corrosion of concrete sewer pipes. Corrosion is the result of a microbial sulfur cycle that develops within the transmission pipe. Sulfate-reducing bacteria consume organic material in the anoxic wastewater, producing H_2S . The latter is oxidized by sulfur-oxidizing chemolithotrophic bacteria that attach to the oxic upper (crown) pipe surface, accelerating corrosion from the production of H_2SO_4 (sulfuric acid).

with natural calcium–aluminum minerals present in the concrete, forming a new mineral that increases internal pressure and contributes to cracking and further acceleration of the corrosion process.

A series of steps and microbial participants similar to those of crown corrosion can corrode concrete holding tanks and cooling towers, particularly those in or near the marine environment where sulfate levels are typically high. Such deterioration can cause slow structural damage, such as concrete chipping, or even lead to a catastrophic rupture with threats to both the environment and humans.

Check Your Understanding

- How does the production of oxalic acid by fungi contribute to the deterioration of stone building materials?
- Which two major microbial physiologies are required to achieve crown corrosion? Which is an aerobic process and which is anaerobic?

CHAPTER REVIEW

I • Mineral Recovery and Acid Mine Drainage

22.1 The capacity of bacteria to oxidize Fe^{2+} aerobically at acidic pH is used to mine metals, principally copper-, uranium-, and gold-containing low-grade ores, through the process of microbial leaching. Bacterial oxidation of Fe^{2+} to Fe^{3+} is the key reaction in most microbial leaching processes because Fe^{3+} can extract metals in the ores under either oxic or anoxic conditions.

Q Which crucial step in the oxidation of copper ores is carried out by *Acidithiobacillus ferrooxidans*? How is copper recovered from copper solutions produced by leaching?

22.2 Spontaneous microbial oxidation of ferrous iron in pyritic ore or coal that has been exposed to air and water, such as occurs during some coal-mining operations, causes a type of pollution called acid mine drainage.

Q Which *Bacteria* and *Archaea* play a major role in acid mine drainage? Why do they carry out the reactions that they do? Why is air necessary for this process?

II • Bioremediation

22.3 Although an inorganic pollutant such as uranium cannot be destroyed, containment is possible by reducing its mobility. For example, metal-reducing microorganisms in a region of

uranium contamination can be stimulated to reduce U^{6+} to U^{4+} , forming the immobile mineral uraninite that does not move into the groundwater.

Q What could thwart microbial bioremediation of a site that contains buried nuclear weapons that are leaking uranium?

22.4 Hydrocarbons are excellent carbon sources and electron donors for bacteria and are readily oxidized when O_2 is available. Hydrocarbon-oxidizing bacteria bioremediate spilled oil, and their activities can be assisted by addition of inorganic nutrients.

Q What physical and chemical conditions are necessary for the rapid microbial degradation of oil in aquatic environments?

22.5 Some xenobiotics persist, whereas others are readily degraded, depending on their chemistries. Chlorinated xenobiotics can be degraded both aerobically and anaerobically. Highly chlorinated xenobiotics can be detoxified by organohalide-respiring bacteria that reductively remove the chlorides. Some oil-based plastics such as PET can be completely degraded by bacteria such as *Ideonella*.

Q Why are some bacterial transformations of xenobiotics possible only through cometabolism? How might *Ideonella sakaiensis* or its enzymes be used in the recycling industry?

III • Wastewater and Drinking Water Treatment

- 22.6** Sewage and industrial wastewater treatment reduces the organic and nutrient load of wastewater. Primary and secondary wastewater treatment employs physical, biological, and physicochemical processes. Following treatment, the effluent water has significantly reduced BOD and is suitable for release into the environment.

Q Trace the treatment of wastewater in a typical plant from incoming water to release. What is the overall reduction in the BOD for typical household wastewater? What is the overall reduction in the BOD for typical industrial wastewater?

- 22.7** Tertiary wastewater treatment for nitrogen and phosphorus removal is used to improve the quality of the wastewater previously subjected to primary and secondary treatment. The increasing use of granular sludge treatment technology offers significant reductions in the energy, space, and chemical requirements of traditional wastewater treatment.

Q Why is tertiary wastewater treatment desirable from an environmental point of view?

- 22.8** Sludge processing is used to reduce the amount of sludge for disposal and produce methane for energy. The anammox process is an effective and efficient way to remove nitrogen from high-ammonia sludge brine. Of increasing concern are pharmaceuticals and ingredients in personal care products that are not degraded by conventional treatment systems and that can have adverse environmental effects, even at very low concentrations.

Q Which of the following are aerobic treatment processes and which are anaerobic: nitrification, anammox, denitrification, sludge digestion to methane?

- 22.9** Drinking water purification plants employ industrial-scale physical and chemical systems that remove or neutralize biological, inorganic, and organic contaminants from water sources. Water purification plants employ clarification, filtration, and chlorination processes to produce potable water.

Q Identify (stepwise) the process of purifying drinking water. What important contaminants are targeted by each step in the process?

- 22.10** The pipes that carry municipal drinking water and the premise plumbing that provide it to the consumer have created new microbial habitats. By forming biofilms on water pipe walls, microbial communities are more resistant to chlorine, can sustain or sequester opportunistic pathogenic bacteria, and its members can be distributed by household water usage.

Q What features of municipal and premise water distribution systems might contribute to a microbial health hazard? Why might showering increase your exposure to opportunistic pathogens?

IV • Indoor Microbiology and Microbially Influenced Corrosion

- 22.11** The indoor air and surfaces of dwellings and other buildings contain a diversity of mostly harmless saprophytic microbes that are typically a reflection of the humans and animals that reside there. However, the microbiota of certain parts of the indoor built environment, such as bathrooms and toilets, may contain enteric pathogens from aerosols generated there.

Q From the perspective of a child's health, can a home be "too clean"? Explain.

- 22.12** Corrosion of metal structures exposed to the environment can be accelerated by microbial activity during microbially influenced corrosion. Structures in or near seawater are particularly prone to corrosion as a consequence of the direct and indirect activities of sulfate-reducing bacteria.

Q How does microbial metabolism accelerate the corrosion of various metals?

- 22.13** Complex microbial communities colonize stone and concrete and produce substances that dissolve and mobilize its mineral constituents. Crown corrosion of concrete sewer lines results from the concerted activities of sulfate-reducing and sulfur-oxidizing bacteria growing within the wastewater and the headspace of sewer pipes, respectively. The resulting sulfuric acid is primarily responsible for the destruction of the concrete.

Q How have fungi adapted in order to survive harsh conditions on stone building materials?

APPLICATION QUESTIONS

1. Acid mine drainage is in part a chemical process and in part a biological process. Discuss the chemistry and microbiology that lead up to acid mine drainage and point out the key reactions that are biological. What ways can you think of to prevent acid mine drainage? How might you prevent further generation of acid drainage?
2. Why is reduction of BOD in wastewater a primary goal of wastewater treatment? What are the consequences of releasing

wastewater with a high BOD into local water sources such as lakes or streams?

3. Discuss the microbial ecology contributing to crown corrosion of concrete sewer lines. In consideration of this ecology, what intervention strategies might be useful in reducing or eliminating corrosion?

CHAPTER GLOSSARY

Acid mine drainage acidic water containing H_2SO_4 derived from the microbial and spontaneous oxidation of iron sulfide minerals released by coal mining

Anaerobic treatment degradative and fermentative reactions carried out by microorganisms under anoxic conditions to treat sludge solids or wastewater containing high levels of insoluble organic materials

Biochemical oxygen demand (BOD) the relative amount of dissolved oxygen consumed by microorganisms for complete oxidation of bioavailable organic and inorganic material in a water sample

Biodeterioration microbially catalyzed processes that degrade stone or concrete

Bioremediation the cleanup of oil, toxic chemicals, and other pollutants by organisms, usually microorganisms

Chloramine a disinfectant chemical manufactured on-site by combining chlorine and ammonia at precise ratios

Chlorination disinfection of water with Cl_2 at a sufficiently high concentration that a residual level is maintained throughout the distribution system

Clarifier a reservoir in which suspended solids in raw water are coagulated and removed through precipitation

Coagulation the formation of large, insoluble particles from much smaller, colloidal particles by the addition of aluminum sulfate and anionic polymers

Crown corrosion the destruction of the upper half, or crown, of concrete wastewater pipes by sulfuric acid produced

through the concerted activities of sulfate-reducing and sulfur-oxidizing bacteria

Effluent water treated wastewater discharged from a wastewater treatment facility

Filtration the removal of suspended particles from water by passing it through one or more permeable media (e.g., sand or activated charcoal) and ion exchangers

Finished water water delivered to the distribution system after treatment

Flocculation the water treatment process after coagulation that uses gentle stirring to cause suspended particles to form larger, aggregated masses (flocs)

Microbial leaching the extraction of valuable metals such as copper from sulfide ores by microbial activities

Microbially influenced corrosion (MIC) the contribution of microbial metabolic activities to accelerating the corrosion of metal structures

Potable drinkable; safe for human consumption

Primary disinfection the introduction of sufficient chlorine or other disinfectant into clarified, filtered water to kill existing microorganisms and inhibit further microbial growth

Primary wastewater treatment physical separation of wastewater contaminants, usually by separation and settling

Pyrite a common iron-containing ore, FeS_2

Raw water surface water or groundwater that has not been treated in any way (also called untreated water)

Reductive dechlorination an anaerobic respiration in which a chlorinated organic compound is used as an electron acceptor, usually with the release of Cl^-

Secondary disinfection the maintenance of sufficient chlorine or other disinfectant residual in the water distribution system to inhibit microbial growth

Secondary wastewater treatment oxidative reactions carried out by microorganisms under aerobic conditions to treat wastewater containing low levels of organic materials

Sediment in treatment of water for drinking, the soil, sand, minerals, and other large particles found in raw water

Sewage liquid effluents contaminated with human or animal fecal material

Suspended solid a small particle of solid pollutant that resists separation by ordinary physical means

Tertiary wastewater treatment any treatment process in which unit operations are added for the further processing of the secondary treatment effluent or solids

Turbidity a measurement of suspended solids in water

Untreated water surface water or groundwater that has not been treated in any way (also called raw water)

Wastewater domestic sewage or liquid industrial waste, which cannot be discarded in untreated form into lakes or streams

Xenobiotic a synthetic compound never produced in nature

MICROBIOLOGYNOW

Coral Fluorescence Provides the Guiding Light for Their Symbiotic Algae

Although many symbiotic microorganisms are transferred directly between generations of their host (vertical transfer), others are acquired from the environment (horizontal transfer) and must find their way to their host. Chemical signaling is one attraction mechanism. However, in at least one symbiosis, light from the green fluorescent protein (GFP) controls the process.

GFP is widely distributed among marine invertebrates, including jellyfish, anemones, and corals. Although often used in protein tagging experiments to measure gene expression and localize specific proteins in the cell, GFP and other proteins that fluoresce in different colors have natural functions that remain unclear. Some possibilities include shifting the color spectrum of bioluminescent organisms for prey attraction or avoidance or functioning in light sensory systems. However, GFP is now known to guide the symbiosis between stony corals (cnidarians) and *Symbiodinium*, the algal symbiont that nourishes the coral.

A significant fraction of *Symbiodinium* acquisition is by horizontal transfer, mostly during the coral larval and juvenile

stages. How does the alga find the coral? The answer lies in the phototaxis of *Symbiodinium* toward light emitted from the coral's GFP (photo). Researchers demonstrated the importance of phototaxis by painting GFP on traps placed in laboratory aquaria containing *Symbiodinium* and in natural reef communities. *Symbiodinium* cells migrated to the painted traps, but not to unpainted traps. The GFP light emission directing *Symbiodinium* phototaxis matched the spectrum optimal for its photosynthesis. Thus, the coral is simply exploiting the natural capacity of *Symbiodinium* to use phototaxis for positioning optimally in the marine light gradient. Phototaxis may also be important for coral reacquisition of their symbionts following a bleaching event. As coral bleaching becomes a more frequent occurrence with climate change, it is essential to better understand mechanisms of repair. Without recovery from bleaching, the major marine ecosystems supported by corals could soon be lost.

Many microbial species form intimate and often mutually beneficial associations, called **symbioses**, with other microorganisms, plants, or animals. In a **mutualism**, both symbiotic partners benefit; in **parasitism**, one symbiotic partner benefits and the other is harmed; in **commensalism**, one symbiotic partner benefits and the other is unaffected. Symbioses typically develop through prolonged association and **coevolution** of the partners, evolution that proceeds jointly in a pair of intimately associated species owing to the effects each has on the other. In this chapter we explore some well-studied examples of these microbial symbioses as a prelude to our coverage in the following chapter of microbial symbioses with humans—symbioses that are not only extensive, but in many instances, absolutely essential for our well-being.

I • Symbioses Between Microorganisms

Microorganisms can form intimate associations of two or more species to use resources more efficiently. Common associations form between phototrophic and chemotrophic partners, such as in lichens and some aquatic bacteria. Other associations exploit conductive surface structures to electrically couple two species for the oxidation of organic carbon.

Many microbial species form mutualisms with other microbial species. Direct microscopic observations of natural samples show that many microbes are not solitary entities but are associated with other microbes on surfaces or as suspended aggregates of cells. In most cases, the advantages conferred by an association are unknown. Because microbial ecologists have recognized that *communities* of interacting microbial populations—not individual organisms—control environmental processes, research to discover the nature of strictly microbial symbioses has increased. In Part I we present three microbial mutualisms where the advantages to both partners are clear.

23.1 Lichens

Lichens are readily visible, leafy or encrusting microbial symbioses often found growing on bare rocks, tree trunks, house roofs, man-made surfaces, and bare soils—surfaces where other organisms typically do not grow (Figure 23.1). The lichen symbiosis originates from an ancient mutualistic association between two dominant microorganisms: a fungus, usually an ascomycete (◀ Section 18.13), and either an alga or a cyanobacterium. This association is one of the earliest forms of terrestrial plant life and can be traced back 400 million years to the Devonian period. The alga or cyanobacterium is the phototrophic partner and produces organic matter that feeds the fungus. The fungus is a chemotroph and provides a firm anchor within which the phototrophic partner can grow. The fungus also releases *lichen acids* that promote the dissolution and chelation of inorganic nutrients from the rock or other surface that are needed by the phototroph. The fungus facilitates the uptake of water and sequesters some for the phototroph, a characteristic that enables lichens to colonize almost all terrestrial environments, including deserts and other arid environments. Cells of the phototroph (also

Lichens are generally categorized by morphology and nearly all can be classified into one of the three types shown here, (a) foliose, (b) fruticose, and (c) crustose.

called the *photobiont*) are embedded in defined layers or clumps among cells of the fungus, together forming the *thallus* (Figure 23.2), and are protected from erosion by rain or wind.

Lichen Components

Lichen photobionts are mostly green algae (◀ Section 18.16) but are sometimes species of brown algae (◀ Section 18.5). When cyanobacteria partner with lichens, they are often nitrogen-fixing species, organisms such as *Anabaena* or *Nostoc* (◀ Sections 3.12 and 15.3). In a few lichens, two phototrophic species are present within a single thallus, and molecular studies have revealed that additional low-abundance species of photobionts can also be co-residents. Variation in the lichen physical structure is primarily determined by the fungus (Figure 23.1), and more than 18,000 species of fungi are able to form lichen associations with a variety of photobionts. Their habitat range spans tropical to polar climatic zones, and coastal to high-altitude habitats. Lichens typically grow quite slowly, with

(a)

(b)

The algal layer is positioned within the lichen structure near the top so as to receive the most sunlight. The fungal partners form the structural layers (cortex) positioned above and below the algal layer.

growth rates varying from 1 mm or less per year to over 3 cm per year, depending on the organisms composing the symbiosis and the temperature and amount of rainfall and sunlight received.

Diversity among the photobionts is lower than that of the fungi, and thus many different kinds of lichens can have the same phototrophic partner. The partner photobiont is primarily determined by lichen reproduction, which may be either asexual or sexual depending on the fungal species. During asexual reproduction, clonally derived fungal propagules co-disperse with the photobiont, preserving the specific symbiotic association. In contrast, fungal spores released by

sexual reproduction lack the photobiont and require independent acquisition of a new symbiotic partner after dispersal. Such transmission provides an opportunity for the fungus to form new symbiotic associations that may have locally adaptive features. In contrast, lichens that disperse by propagules have less adaptive flexibility.

Molecular Studies of Lichens

The conventional view that lichens are simple two-partner assemblages has been challenged by culture-independent molecular studies (◀ Section 19.6) showing that in addition to multiple photobionts, lichens may have more than one fungus and also host bacteria that may benefit the association. The cortex of many lichens, formed by fungal structural tissue bounding the phototroph layer (Figure 23.2), can also contain a yeast (basidiomycete, ◀ Section 18.14) in addition to the ascomycete. Similarly, a common feature of many lichens is association with *Alphaproteobacteria* of the order *Rhizobiales*—known N_2 -fixing bacteria—suggesting that in addition to cyanobacteria, other organisms may contribute fixed nitrogen to the symbiosis.

Metagenomic and metabolomic studies (◀ Sections 10.7, 10.10, and 19.8) have identified other metabolic benefits of the bacterial association, including the production of vitamins and protection from toxic compounds. A striking example of the latter is the increased abundance of genes encoding arsenic resistance detected in lichens inhabiting environments contaminated with arsenic. These examples demonstrate how culture-independent methods can reveal exciting new information about even well-studied symbioses.

Check Your Understanding

- What two types of microbes form a partnership in the lichen symbiosis? What are the benefits to both partners?
- Besides organic compounds, of what benefit to the fungus is a mutualism with *Anabaena*?
- What might be advantages of having bacteria present in the lichen symbiosis?

23.2 “*Chlorochromatium aggregatum*”

Microbial mutualisms called **consortia** form in freshwater environments. A commonly observed consortium develops between non-motile green sulfur bacteria (phototrophs that are colored either green or brown) and certain motile, nonphototrophic bacteria. These consortia are found worldwide in stratified sulfidic freshwater lakes and can account for up to 90% of the green sulfur bacteria present and nearly 70% of the bacterial biomass in these lakes. The basis of the mutualism of these consortia is in the phototrophic production of organic matter by the green sulfur bacterium and the motility and organic matter consumption of the chemotrophic partner organism. Each consortium has been given a genus and species name, but since these names do not denote true species (because they are not a single organism), the names are enclosed in quotation marks. We examined the general biology of these consortia in Section 15.6.

Nature of the Consortium

The morphology of a green sulfur bacterial consortium depends on its species composition. The consortium generally consists of 13–69

Figure 23.3 Drawings of some motile phototrophic green bacterial consortia found in freshwater lakes. Green epibionts: (a) "*Chlorochromatium aggregatum*," (b) "*C. glebulum*," (c) "*C. magnum*," (d) "*C. lunatum*." Brown epibionts: (a) "*Pelochromatium roseum*," (d) "*P. selenoides*." The epibionts are 0.5–0.6 μm in diameter. Adapted from Overmann, J., and H. van Gernerden. 2000. *FEMS Microbiol. Rev.* 24: 591.

green sulfur bacteria, called *epibionts*, surrounding and attached to a central, colorless, flagellated, rod-shaped bacterium (Figure 23.3). Several distinct motile phototrophic consortia have been recognized based on the color, morphology, and presence or absence of gas vesicles (Section 2.7) of the epibionts. For example, in "*Chlorochromatium aggregatum*" the central bacterium is surrounded by rod-shaped green bacteria, whereas in "*Pelochromatium roseum*" the epibiont is brown. The consortium "*Chlorochromatium glebulum*" is bent and includes green epibionts that contain gas vesicles (Figure 23.3).

Green sulfur bacteria are obligately anaerobic phototrophs that form a distinct phylum (*Chlorobi*, Section 15.6). The green and brown species differ in the types of bacteriochlorophyll and carotenoids they contain. Both green and brown species are found in stratified lakes where light penetrates to depths at which the water contains hydrogen sulfide (H_2S), the primary electron donor for photosynthetic CO_2 fixation by the phototroph. In stratified lakes, the motile consortia reposition rapidly to remain in regions where conditions are most favorable for photosynthesis in the constantly changing gradients of light, oxygen, and sulfide that occur throughout the course of a day. Water samples collected from depths where these conditions are most favorable are enriched in this morphologically conspicuous consortium (Figure 23.4). The consortia show dark aversion (scotophobicity, Section 2.12) and positive chemotaxis toward sulfide.

Some free-living green sulfur bacteria, such as *Pelodictyon* (*Chlorobium*) *phaeoclathratiforme*, produce gas vesicles that regulate buoyancy and vertical position in the water column. However, because they are so small, the time they require for repositioning in the water column is from one to several days, which is not fast enough for tracking the more rapidly changing gradients. By contrast, motile consortia move up and down in the water column fast enough to follow the gradients of light and sulfide as they change on a diel basis.

Although green bacterial consortia were discovered almost a century ago, only with the advent of molecular techniques and newer culture methods has it become possible to study certain aspects of these remarkable associations. Sequencing of 16S ribosomal RNA (rRNA) genes revealed a significant geographic distribution of

epibionts in lakes of Europe and the United States, many of which were genetically distinct. Epibionts in neighboring lakes have identical 16S rRNA gene sequences, whereas the sequences of morphologically similar epibionts in widely separated lakes differ. Phylogenetic analysis indicates that mechanisms of cell–cell recognition between epibionts and their central bacterium arose through coevolution of each specific partnership.

Phylogeny and Metabolism of a Consortium

The epibiont of "*Chlorochromatium aggregatum*" has been isolated and grown in pure culture. Although this green sulfur bacterium, named *Chlorobium chlorochromatii*, can be grown in pure culture, no naturally free-living variant has been observed, supporting the view that in nature a symbiotic lifestyle is obligate for epibionts. The central bacterium of "*Chlorochromatium aggregatum*" is a species of *Betaproteobacteria* (Section 16.2). This bacterium requires α -ketoglutarate (an intermediate of the citric acid cycle, Figure 3.12) for growth, and this is presumably supplied to it by the epibiont. However, the central cell only assimilates fixed carbon in the presence of light and sulfide—conditions in which the epibionts are active and can transfer nutrients to the central bacterium. Genomic analysis of the central bacterium of one consortium revealed massive gene loss, indicating that this organism is unable to grow independently of the green sulfur bacterium.

Recent studies comparing the transcriptome and proteome (Sections 10.8 and 10.9) of *C. chlorochromatii* growing alone or in association with the central rod bacterium have identified some features specifically related to the symbiosis. Approximately 50 *C. chlorochromatii* proteins are unique to the symbiotic state. Most of approximately 350 differentially regulated genes are repressed when the organism is symbiotically associated, whereas only 19 genes are more highly expressed. Many of the more highly expressed genes encode proteins of amino acid metabolism and nitrogen regulation. These include the enzyme glutamate synthase (Section 3.14) and a transport protein for branched amino acids, suggesting that in addition to α -ketoglutarate, the metabolic coupling between the epibiont and central bacterium involves the exchange of amino acids as well.

Figure 23.4 Phase-contrast micrograph of "*Pelochromatium roseum*" from Lake Dagow (Brandenburg, Germany). The preparation was compressed between a coverslip and microscope slide to reveal the central rod-shaped bacterium (arrow). A single consortium is about 3.5 μm in diameter. Figure 23.5 Scanning electron micrographs of “*Chlorochromatium aggregatum*.”

(a) *Chlorobium chlorochromatii* epibionts tightly clustered around a flagellated central bacterium. (b) The central bacterium exhibits numerous protrusions of its outer membrane that make intimate contact with the epibionts, possibly fusing the periplasms of the two gram-negative organisms. Cells of the epibiont are about 0.6 μm in diameter. Used with permission from G. Wanner et al. 2008. *J. Bacteriol.* 190: 3721.

Scanning electron microscopy of the consortium (Figure 23.5) has revealed that tubular extensions of the central bacterium’s periplasm (◀ Section 2.4) cover much of its surface and appear to fuse with the periplasm of the epibiont. If the two bacterial partners actually share a common periplasmic space, this would facilitate the transfer of nutrients from phototroph to chemotroph and vice versa (however, whether the chemotroph reciprocates and transfers nutrients to the phototroph is unknown). The fact that the central bacterium is unable to grow without its phototrophic partner (while the phototroph can be grown in pure culture), and that organic compounds are only assimilated by the chemotroph in the light, is strong evidence that nutrients flow from the phototroph to feed the chemotroph and that the chemotroph is obligatorily dependent on its phototrophic partner.

Check Your Understanding

- What is the evidence that “*Chlorochromatium aggregatum*” is a stable product of evolution?
- What advantage does motility offer a phototrophic consortium?
- How might nutrients be shuttled between phototroph and chemotroph in the consortium?

23.3 Methanotrophic Consortia: Direct Interspecies Electron Transfer

Methanotrophic consortia that couple the activities of two anaerobic microbes effectively oxidize methane to CO_2 in anoxic marine sediments. The biochemistry of this process was discussed in Section 14.16.

Anaerobic Oxidation of Methane and Short-Chain Alkanes

It has long been known that methane is oxidized in anoxic marine sediments. Subsequent culture-independent studies showed that specific methane-oxidizing (methanotrophic) *Archaea* form intimate associations with sulfate-reducing bacteria (Figure 23.6a) to do this, and working together, the organisms carry out the following reaction:

The methanotrophic *Archaea* comprise three different groups of anaerobic methane (ANME)-oxidizing *Euryarchaeota*. Members of the ANME-1 cluster belong to the *Methanomicrobia*, ANME-2 the order *Methanosarcinales*, and ANME-3 to *Methanococcoides* species (◀ Section 17.2).

All ANME *Archaea* employ part of the metabolic pathway used by methanogens to generate methane, but ANME run the pathway in the opposite direction. The first step of anaerobic oxidation is activation of methane by methyl-coenzyme M reductase (MCR), producing coenzyme M-bound methyl groups that are further oxidized by

(a)

(b)

Viola Krukenberg, Karin Knittel, and Gunther Wegener

Figure 23.6 Anaerobic methane-oxidizing consortia. (a) A methanotrophic consortia enriched from geothermally heated sediments (Guaymas Basin, Gulf of California, Mexico) by cultivation with methane as sole electron donor and stained by CARD-FISH (◀ Section 19.5) using probes selective for the ANME methanotroph (red fluorescence) and its sulfate-reducing bacterial partner (green fluorescence). (b) Electron micrograph of a thin section through the consortia, showing the electrically conductive “nanowires” produced by the sulfate reducer (H), connecting it electrically to cytochrome-rich proteins on the surface of the ANME methanotroph (A).

the C_1 pathway (◀ Section 14.15). Some species of ANME belonging to the *Methanomicrobia* can completely oxidize short-chain alkanes (ethane, propane, and butane) using variants of MCR that activate the alkanes for further oxidation in a similar fashion to how MCR activates methane in ANME species. For example, ethane-oxidizing enrichment cultures produce ethyl-coenzyme M (ethyl-CoM) as an initial intermediate. Despite this variation in substrates, short-chain alkane oxidizers depend on syntrophic interactions with a sulfate reducer or other appropriate electron-accepting partner bacteria.

Sulfate-Reducing Bacteria as Partner Organisms in Anoxic Hydrocarbon Oxidations

A variety of sulfate-reducing *Bacteria* are syntrophic partners, including the *Deltaproteobacteria* *Desulfosarcina* and *Desulfococcus* species, and species of the family *Desulfobulbaceae* (◀ Section 15.11). These bacteria accept electrons from hydrocarbon-oxidizing methanogens and dispose of them by reducing sulfate to sulfide. The transfer of electrons occurs by direct electron transfer between the two species, using electrically conductive appendages similar to those described for metal-reducing bacteria (◀ Sections 14.13, 15.13, and 21.5 and Figures 14.31 and 21.14). The conductive structures (also called “nanowires”) bridge the intercellular space between the organisms (Figure 23.6b).

Anaerobic methane oxidation may not depend on syntrophic association in all cases. For example, enrichment cultures dominated by certain ANME *Archaea* established from freshwater samples were shown to couple methane oxidation to the reduction of nitrate to nitrite, rather than to the reduction of sulfate. In addition, some evidence suggests that redox-active metals such as ferric iron may also function as electron acceptors to support anoxic methanotrophy. However, in both of these cases the presence of a second organism (the electron consumer) to form a syntrophic association cannot be ruled out, as pure cultures of ANME organisms have not yet been obtained.

Direct Interspecies Electron Transfer (DIET)

Direct interspecies electron transfer (abbreviated DIET) of the type that drives the ANME–sulfate reducer association is much more common than was earlier suspected. For example, apart from the direct reduction of insoluble metals by *Geobacter* species (◀ Section 21.5), species of *Geobacter* also form partnerships with methanogens. When paired in an association with *G. metallireducens*, the normally acetate-utilizing (acetoclastic) methanogen *Methanosaeta harundinacea* reduces carbon dioxide to methane using electrons delivered by *G. metallireducens* from acetate oxidation. In this partnership, *Geobacter* benefits because it uses the acetate as its carbon and energy source. And, because abiotic electron acceptors are limiting or absent, *Geobacter* uses the methanogen as its electron acceptor. The methanogen benefits because instead of splitting acetate to form methane, it reduces CO_2 to CH_4 instead, a more energetically favorable reaction (◀ Section 14.15). As we learn more about organisms participating in DIET, greater metabolic variety will almost surely be revealed.

Check Your Understanding

- What observations suggest that direct interspecies electron transfer may be more widely distributed among *Bacteria* and *Archaea* than now recognized?

- Which of the two partner organisms, the ANME or the sulfate-reducing bacterium, may have the capacity to live independently? How might this influence the specificity of interaction?

II • Plants as Microbial Habitats

Symbiotic associations between microorganisms and plants can be mutualistic, where the microbe and the plant exchange nutrients, or parasitic, where the plant produces nutrients only for the bacterium. Prime examples of the former exist in the *Rhizobium*–root nodule symbiosis and of the latter in crown gall disease.

Plants interact closely with microbes through their roots and leaf surfaces and even more intimately within their vascular tissue and cells. Most mutualisms between plants and microorganisms increase nutrient availability to the plants or defend them against pathogens. We consider three examples in the next three sections: (1) a mutualism where the nature of the symbiosis is understood in exquisite detail (root nodules), (2) a mutualism in which plants expand and interconnect their root system through association with a fungus (mycorrhizae), and (3) a symbiosis that is harmful to the plant (crown gall disease).

23.4 The Legume–Root Nodule Symbiosis

A plant–bacterial mutualism of great importance to humans is that of leguminous plants and nitrogen-fixing bacteria. *Legumes* are flowering plants that bear their seeds in pods and include such agriculturally important members as soybeans, clover, alfalfa, beans, and peas. These crops are key commodities for the food and agricultural industries, and the ability of legumes to grow without added nitrogen saves farmers millions of dollars in fertilizer costs yearly and reduces the polluting effects of fertilizer runoff.

The partners in a symbiosis are called *symbionts*, and most nitrogen-fixing bacterial symbionts of plants are collectively called *rhizobia*, derived from the name of a major genus, *Rhizobium*. Species of rhizobia are *Alpha*- or *Betaproteobacteria* (Figure 23.7; ◀ Sections 16.1

Figure 23.7 Phylogeny of rhizobial (genus names in boldface) and related genera inferred from analysis of 16S rRNA gene sequences. More than 70 species of rhizobia are found in 12 genera of *Alpha*- and *Betaproteobacteria*.

and 16.2) that can grow freely in soil or infect leguminous plants and establish a symbiotic relationship. The same bacterial genus (or even species) of legume can contain both rhizobial and nonrhizobial strains of nitrogen fixers. Infection of legume roots by rhizobia leads to the formation of **root nodules** (Figure 23.8) in which the bacteria convert N_2 to NH_3 (◀ Sections 3.12 and 15.9). Nitrogen fixation in root nodules accounts for a fourth of the N_2 fixed annually on Earth and is of enormous agricultural importance, as it increases the fixed nitrogen content of soil. Nodulated legumes can grow well on unfertilized bare soils that are nitrogen deficient, while other plants grow only poorly on them (Figure 23.9).

Leghemoglobin and Cross-Inoculation Groups

In the absence of its bacterial symbiont, a legume cannot fix N_2 . Rhizobia, on the other hand, can fix N_2 when grown in pure culture under microaerophilic conditions (a low-oxygen environment is necessary because the key nitrogen-fixing enzyme *nitrogenase* is inactivated by high levels of O_2 , ▶ Section 3.12). In the nodule, O_2 levels are precisely controlled by the O_2 -binding protein **leghemoglobin**. Production of this iron-containing protein in healthy N_2 -fixing nodules (Figure 23.10) is induced through the interaction of the plant and bacterial partners. Leghemoglobin functions as an “oxygen buffer,” cycling between the oxidized (Fe^{3+}) and reduced (Fe^{2+}) forms of iron to supply sufficient O_2 for bacterial respiration while keeping unbound O_2 within the nodule low. The ratio of leghemoglobin-bound O_2 to free O_2 in the root nodule is thus maintained on the order of 10,000:1.

There is a marked specificity between the species of legume and rhizobium that can establish a symbiosis. A particular rhizobial species is able to infect certain species of legumes but not others. A group of related legumes that can be infected by a particular rhizobial species is called a *cross-inoculation group*. Each group consists of all the legume

species that will develop nodules when inoculated with rhizobia obtained from any other legume of the group (Table 23.1). If legumes are inoculated with the correct rhizobial strain, leghemoglobin-rich, N_2 -fixing nodules develop on their roots (Figures 23.8–23.10).

Steps in Root Nodule Formation

How root nodules form is well understood, and the steps are as follows (Figure 23.11):

1. Recognition of the correct partner by both plant and bacterium and attachment of the bacterium to the root hairs
2. Secretion of oligosaccharide signaling molecules (Nod factors) by the bacterium
3. Bacterial invasion of the root hair
4. Movement of bacteria to the main root by way of the infection thread
5. Formation of modified bacterial cells (bacteroids) within the plant cells, development of the N_2 -fixing state, and continued plant and bacterial cell division forming the mature root nodule

Joe Burton

Figure 23.11 Steps in the formation of a root nodule in a legume infected by *Rhizobium*. Formation of the bacteroid state is a prerequisite for nitrogen fixation. The time course of nodulation events from infection to effective nodule is about 1 month for soybeans. See Figure 23.16 for physiological activities in the nodule.

Attachment and Infection

The roots of leguminous plants secrete organic compounds that stimulate the growth of a diverse rhizosphere microbial community. If rhizobia of the correct cross-inoculation group are in the soil, they will form large populations and eventually attach to the root hairs that extend from the roots of the plant (Figure 23.11). An adhesion protein called *rhicadhesin* is present on the cell surfaces of rhizobia. Other substances, such as carbohydrate-containing proteins called *lectins* and specific receptors in the plant cytoplasmic membrane, also play roles in plant–bacterium attachment.

After attaching, a rhizobial cell penetrates into the root hair, which curls in response to substances (Nod factors) secreted by the bacterium. The bacterium then induces the plant to form a cellulosic tube, called the **infection thread** (Figure 23.12a), which spreads

down the root hair. Root cells adjacent to the root hairs subsequently become infected by rhizobia, and plant cells divide. Continued plant cell division forms the tumorlike nodule (Figure 23.12a) consisting of plant cells filled with bacteroids (discussed below and shown in Figure 23.12b, c). A different mechanism of infection is used by some rhizobia adapted to aquatic or semiaquatic tropical legumes (see Figure 23.17). These rhizobia enter the plant at the loose cellular junctions of roots emerging perpendicular from an established root (*lateral roots*), or on a stem in or just above the water. Following entry into the plant, some of the rhizobia develop infection threads, whereas others do not.

Bacteroids

The rhizobia multiply rapidly within the plant cells and become transformed into swollen, misshapen, and branched cells called **bacteroids**. A microcolony of bacteroids becomes surrounded by portions of the plant cytoplasmic membrane to form a structure called the *symbiosome* (Figure 23.12c), and only after the symbiosome forms does N_2 fixation begin. Nitrogen-fixing nodules can be detected experimentally by the reduction of acetylene to ethylene (◀ Section 19.9). When the plant dies, the nodule deteriorates, releasing bacteroids into the soil. Although bacteroids are incapable of division, a small number of dormant rhizobial cells are always present in the nodule. These now proliferate, using some of the products of the deteriorating nodule as nutrients. The bacteria can then initiate infection the next growing season or maintain a free-living existence in the soil.

Nodule Formation: *nod* Genes, Nod Proteins, and Nod Factors

Rhizobial genes that direct the steps in nodulation of a legume are called *nod* genes. It is thought that the ability to form nodules has independently emerged multiple times through the horizontal transfer of such genes as *nod* and *nif* that are located on plasmids or

Figure 23.12 The infection thread and formation of root nodules. (a) Light micrograph of an early-stage nodule from a legume (*Lotus japonicus*) infected with a rhizobium strain containing the *lacZ* gene. The nodule was sectioned and bacterial distribution (blue) determined using an activity stain (X-gal) that turns blue when cleaved by the enzyme β -galactosidase (Section 12.2 and Figure 12.10). An infection thread, consisting of a cellulosic tube through which bacteria move to root cells, is clearly visible extending from the surface to the interior. (b) Transmission electron micrograph through a soybean nodule infected with *Bradyrhizobium japonicum*, showing bacteroid-filled plant cells. The plant cell is approximately 50 μm long. (c) Higher-magnification micrograph showing individual symbiosomes, each filled with several bacteroids. The clear areas in each bacteroid are the storage polymer poly- β -hydroxybutyrate (Section 2.7). Bacteroids are about 2 μm long.

transferable regions of chromosomal DNA. In *Rhizobium leguminosarum* biovar *viciae*, which nodulates peas, ten *nod* genes have been identified. The *nodABC* genes encode proteins that produce oligosaccharides called **Nod factors**; these induce root hair curling and trigger cell division in the pea plant, eventually leading to formation of the nodule (see Figure 23.16 for a description of root nodule biochemistry).

Nod factors are lipochitin oligosaccharides to which various substituents are bonded (Figure 23.13) that function as primary rhizobial signaling molecules triggering legumes to develop new plant organs: root nodules that host the bacteria as nitrogen-fixing bacteroids (Figure 23.12). Resolving the details of the signaling pathway triggered by Nod binding to cell surface receptors (NFR1 and NFR2) and leading to the induction of organogenesis (nodule formation) is an active area of research (Figure 23.14). Interestingly, many elements of the signaling pathway leading to nodulation are also used by the mycorrhizal fungi for infection of plant roots (Figure 23.14 and Section 23.5).

Which plants a given rhizobial species can infect is in part determined by the structure of the Nod factor it produces. Besides the *nodABC* genes, which are universal and whose products synthesize the Nod backbone, each cross-inoculation group contains *nod* genes that encode proteins that chemically modify the Nod factor backbone to form its species-specific molecule (Figure 23.13). In *R. leguminosarum* biovar *viciae*, *nodD* encodes the regulatory protein NodD, which controls transcription of other *nod* genes. After interacting with inducer molecules, NodD promotes transcription and is thus a positive regulatory protein (Section 7.3). NodD inducers are plant flavonoids, organic molecules that are widely secreted by plants. Some flavonoids that are structurally very closely related to *nodD* inducers in *R. leguminosarum* biovar *viciae* inhibit *nod* gene expression in other rhizobial species (Figure 23.15). This indicates that part of the specificity observed between plant and bacterium in the rhizobia–legume symbioses is controlled by the chemistry of the flavonoids secreted by each species of legume.

Biochemistry of Root Nodules

As discussed in Section 3.12, N_2 fixation is catalyzed by *nitrogenase*. Nitrogenase from bacteroids shows the same biochemical properties as the enzyme from free-living N_2 -fixing bacteria, including O_2 sensitivity and the ability to reduce acetylene as well as N_2 . Bacteroids are dependent on the plant for the electron donor for N_2 fixation.

the water level. The general sequence of events by which stem nodules form in *Sesbania* resembles that of root nodules: attachment, formation of an infection thread, and bacteroid formation.

Some stem-nodulating rhizobia produce bacteriochlorophyll *a* and thus have the potential to carry out anoxygenic photosynthesis (◀ Section 14.5) in their illuminated habitat. Bacteriochlorophyll-containing rhizobia, called “photosynthetic *Bradyrhizobium*,” are widespread in nature, particularly in association with tropical legumes. In these species, light energy converted to chemical energy (ATP) in photosynthesis probably supplies part of the energy source needed by the bacterium to support N_2 fixation.

Nonlegume N_2 -Fixing Symbioses: *Azolla*–*Anabaena* and *Alnus*–*Frankia*

Various nonleguminous plants form N_2 -fixing symbioses with bacteria other than rhizobia. For example, the water fern *Azolla* harbors

Figure 23.18 *Azolla*–*Anabaena* symbiosis. (a) Intact association showing a single plant of *Azolla pinnata*. The diameter of the plant is approximately 1 cm. (b) Cyanobacterial symbiont *Anabaena azollae* as observed in crushed leaves of *A. pinnata*. Single cells of *A. azollae* are about 5 μm wide. Vegetative cells are oblong; the spherical heterocysts (lighter color, arrows) are differentiated for nitrogen fixation.

Figure 23.19 *Frankia* nodules and *Frankia* cells. (a) Root nodules of the common alder *Alnus glutinosa*. (b) *Frankia* culture purified from nodules of *Comptonia peregrina*. Note vesicles (arrows) on the tips of hyphal filaments.

within small pores of its fronds a species of heterocystous N_2 -fixing cyanobacteria (◀ Section 15.3) called *Anabaena azollae* (Figure 23.18). *Azolla* has been used for centuries to enrich Asian rice paddies with fixed nitrogen. Before planting rice, the farmer allows the surface of the rice paddy to become densely covered with *Azolla*. As the rice plants grow, they eventually crowd out the *Azolla*, causing its death and the release of its nitrogen, which is assimilated by the rice plants. By repeating this process each growing season, rice farmers can obtain high yields of rice without applying nitrogenous fertilizers.

The alder tree (genus *Alnus*) has N_2 -fixing root nodules (Figure 23.19a) that harbor filamentous, N_2 -fixing actinomycetes of the genus *Frankia*. When assayed in cell extracts the nitrogenase of *Frankia* is sensitive to O_2 , but cells of *Frankia* fix N_2 at full oxygen tensions. This is because *Frankia* protects its nitrogenase from O_2 by localizing the enzyme in terminal swellings on the cells called *vesicles* (Figure 23.19b). The vesicles contain thick walls that retard O_2 diffusion, thus maintaining the O_2 tension within vesicles at levels compatible with nitrogenase activity. In this regard, *Frankia* vesicles resemble the heterocysts produced by some filamentous cyanobacteria as localized sites of N_2 fixation (◀ Sections 8.9 and 15.3).

Alder is a characteristic pioneer tree able to colonize nutrient-poor soils, probably because of its ability to enter into a symbiotic N_2 -fixing relationship with *Frankia*. A number of other small or bushy, woody plants are nodulated by *Frankia*. As is the case for the rhizobial symbionts of leguminous plants, a single strain of *Frankia* can form nodules on several different species of plants.

23.5 Mycorrhizae

Mycorrhizae are mutualisms between plant roots and fungi in which nutrients are transferred in both directions. The fungus transfers inorganic nutrients—in particular, phosphorus and nitrogen—from the soil to the plant, and the plant in turn transfers primarily carbohydrates to the fungus. These mutualisms are harnessed in agricultural applications. From fungal spores produced in culture or from root scrapings of infected plants, soil inoculants are produced that enhance plant growth.

Classes of Mycorrhizae

There are two classes of mycorrhizae. In *ectomycorrhizae*, fungal cells form an extensive sheath (*fungal mantle*) around the *outside* of the root with only a slight penetration into the root cellular structure (Figure 23.20). As rootlets emerge, they are rapidly colonized by the fungi (Figure 23.20a). In *endomycorrhizae*, a part of the fungus becomes deeply embedded within cells comprising the root tissue. Ectomycorrhizae are found mainly on the roots of forest trees, especially conifers, beeches, and oaks, and are most highly developed in boreal and temperate forests. In such forests, almost every root of every tree is mycorrhizal. The root system of a mycorrhizal tree such as a pine (genus *Pinus*) is composed of both long and short roots (Figure 23.20b, c). The short roots, which are characteristically dichotomously branched in *Pinus* (Figure 23.20b, c), show typical fungal colonization, and long roots are also frequently colonized.

Ectomycorrhizal hyphae extending from the fungal mantle and penetrating between the epidermal and cortical cells form a network called the *Hartig net* (Figure 23.20d) where nutrient exchange between the fungus and the host plant occurs that benefit the plant (see Figure 23.23). Most mycorrhizal fungi do not catabolize cellulose and other leaf litter polymers. Instead, they catabolize simple

carbohydrates and typically have one or more vitamin requirements. They obtain their carbon from root secretions and obtain inorganic minerals from the soil. Mycorrhizal fungi are rarely found in nature except in association with roots, and most are probably obligate symbionts.

Despite the close symbiotic association between fungus and root, a single species of tree can form multiple mycorrhizal associations. One pine species can associate with over 40 species of fungi. This relative lack of host specificity allows ectomycorrhizal mycelia to interconnect trees, providing linkages for transfer of carbon and other nutrients between trees of the same or different species. Nutrient transfer from well-illuminated overstory plants to shaded trees is thought to help equalize resource availability, subsidizing young trees and increasing biodiversity by promoting the coexistence of different species.

Arbuscular Mycorrhizae

Although ectomycorrhizal fungi play a significant role in the ecology of forests, there is a greater diversity of endomycorrhizae. Most are *arbuscular mycorrhizae* (AM) that comprise a phylogenetically distinct fungal division, the *Glomeromycota* (◀ Section 18.12), of which all or most species are obligate plant mutualists (the word *arbuscular* means “little tree”). AM colonize 70–90% of all terrestrial plants, including most grassland species and many crop species. The association between plants and the *Glomeromycota* is thought to be the ancestral type of mycorrhizae, established about 450 million years ago and an important evolutionary step in the successful invasion of dry land by terrestrial plants.

AM fungi produce lipochitin oligosaccharide signaling factors (**Myc factors**) closely related to the Nod factors in the rhizobium–legume symbiosis (Section 23.4), and Myc factors initiate formation

Figure 23.20 Ectomycorrhizal colonization of pine and beech tree roots. (a) Confocal image of an ectomycorrhizal fungus (stained green) aggregating on an emerging tree rootlet (stained red) and then “running” on the surface as it begins to further colonize the root. (b) Colonization of pine (*Pinus sylvestris*) roots with the ectomycorrhizal fungus *Suillus bovinus*. (c) Ectomycorrhizal root tips of pine roots enclosed by a mantle of ectomycorrhizal fungi (white) and associated hyphae extending into the soil matrix. The ectomycorrhizal fungus *Suillus bovinus* also forms rhizomorphs, hyphal aggregations that are involved in the long-distance transport from the soil to the mycorrhizal root. (d) Cross section of a thin beech root showing the fungal mantle (FM) and Hartig net (HN) within the root cortex (C). The Hartig net is the location of nutrient exchange between the plant and fungus. Also shown are root vascular tissue (ST) and endodermis (E).

UNIT

of the mycorrhizal state (Figures 23.13 and 23.14). Root colonization by an AM fungus begins with germination of a soilborne spore, producing a branched germination mycelium that recognizes the host plant through reciprocal chemical signaling. Spore germination and mycelial branching is induced by *strigolactones* (Figure 23.21a, b), plant hormones released by the roots that also play a key role in plant development. When a plant is nutrient-limited, this hormone represses aboveground plant growth (suppressing formation of secondary shoots) and stimulates the growth of the root system, enhancing the production of lateral roots and root hairs. These developmental changes help the plant secure nutrients before using them later for aboveground growth.

The Myc factor produced by the AM fungal mycelium signals the plant to initiate the developmental process (Figure 23.14). The fungus then forms a contact structure called the *hyphopodium* with root epidermal cells (Figure 23.21c). Penetrating hyphae extend into the plant from each hyphopodium, usually forging an intracellular path through epidermal and outer cortical cell layers of the root before forming dichotomously branched or coiled hyphal structures called **arbuscules** within plant inner cortex cells, near vascular tissues (Figure 23.21c, d). However, the arbuscular hyphae remain separated from plant protoplasm by an extensive plant cytoplasmic membrane that forms a region called the *apoplast* (Figure 23.22), and this structure

Figure 23.22 Pathways of N, P, and C exchange between plant and arbuscular mycorrhizal fungi. Inorganic nitrogen (NH_4^+ and NO_3^-) and phosphorus (P_i) mined from the soil by the extraradical (soil-associated) mycelia are translocated to the plant as arginine and polyphosphate (poly-P) through the mycelial network and delivered to the plant at the intraradical (plant cell-associated) mycelium. Ammonia and phosphate are regenerated in the intraradical mycelium for transfer to the plant cell. In exchange for the N and P, the plant provides organic carbon to the fungus.

Sergey Ivanov and Maria Harrison

functions to increase the surface area of contact between plant and fungus. Inorganic nitrogen and phosphorus are then “mined” from the soil by the fungi, converted to arginine and polyphosphate, and translocated through the hyphae to the plant (Figure 23.22).

Myc factors are very similar to the rhizobial Nod factors and only relatively minor modifications of the chitin backbone structure confer specificity (Figure 23.13). It is likely that the basic signaling and developmental systems used in the legume–root nodule symbiosis (Section 23.4), which arose about 60 million years ago, first evolved in the much more ancient AM fungi–plant symbiosis and were recruited and adapted for the legume–root nodule symbiosis (Figure 23.14).

Although the arbuscular mycorrhizae are a much more ancient and widely distributed microorganism–plant symbiosis, understanding of their signaling and developmental program has been slower to develop because AM fungi cannot be grown in pure culture. AM fungi are obligately *biotrophic* (meaning that they obtain their nutrients only from living cells of their symbiotic partner), and unlike rhizobia, they have no supporting genetic system that can be exploited to unravel the developmental steps leading to the plant–fungus association.

Benefits for the Plant

The beneficial effect of the mycorrhizal fungus on the plant is best observed in poor soils where plants that are mycorrhizal thrive, but nonmycorrhizal ones do not. For example, if trees planted in prairie soils, which ordinarily lack a suitable fungal inoculum, are artificially inoculated at the time of planting, they grow much more rapidly than uninoculated trees (Figure 23.23). The mycorrhizal plant can absorb nutrients from its environment more efficiently (Figure 23.22) and

thus has a competitive advantage. This improved nutrient absorption is due to the greater surface area provided by the fungal mycelium (see Figure 23.23 inset). In the pine seedling shown in Figure 23.20b and c, the ectomycorrhizal fungal mycelium makes up the overwhelming part of the absorptive capacity of the plant root system. The mycorrhizal plant is better able to function physiologically and compete successfully in a species-rich plant community, and the fungus benefits from a steady supply of organic nutrients.

In addition to helping plants absorb nutrients, mycorrhizae also play a significant role in supporting plant diversity. Field experiments clearly show a positive correlation between the abundance and diversity of mycorrhizae in a soil and the extent of the plant diversity that develops in it. However, although most mycorrhizae are true mutualistic symbioses, there are also parasitic mycorrhizae. In these less common mycorrhizal symbioses, either the plant parasitizes the fungus or, in some cases, the fungus parasitizes the plant.

There is much more to learn about fungal–plant symbioses, and such discoveries will be important not only in agriculture but also in facilitating the restoration of damaged ecosystems.

- How do mycorrhizal fungi promote plant diversity?

23.6 *Agrobacterium* and Crown Gall Disease

Some microorganisms develop parasitic symbioses with plants. The genus *Agrobacterium*, a relative of the root nodule bacterium *Rhizobium* (Section 23.4), is such an organism, causing the formation of tumorlike growths on diverse plants. The two species of *Agrobacterium* most widely studied are *Agrobacterium tumefaciens* (also called *Rhizobium radiobacter*), which causes *crown gall disease*, and *Agrobacterium rhizogenes* (also called *Rhizobium rhizogenes*), which causes *hairy root disease*.

The Ti Plasmid

Although wounded plants often form a benign accumulation of tissue called a *callus*, the growth in crown gall disease (Figure 23.24) is different in that it is uncontrolled growth, resembling an animal tumor. *A. tumefaciens* cells induce tumor formation only if they contain a large plasmid called the **Ti plasmid** (Ti for tumor inducing). In *A. rhizogenes*, a similar plasmid called the *Ri plasmid* is necessary for induction of hairy root disease. Following infection, a part of the Ti plasmid called the *transferred DNA* (T-DNA) is integrated into the plant's genome. T-DNA carries the genes for tumor formation and also for the synthesis of a number of modified amino acids called *opines*. *Octopine* [N^2 -(1,3-dicarboxyethyl)-L-arginine] and *nopaline* [N^2 -(1,3-dicarboxypropyl)-L-arginine] are two common opines. Opines are produced by plant cells transformed by T-DNA and are a source of carbon and nitrogen, and sometimes phosphate, for the parasitic *A. tumefaciens* cells. These nutrients are the benefits for the bacterial symbiont.

Figure 23.23 Effect of mycorrhizal fungi on plant growth. Six-month-old seedlings of Monterey pine (*Pinus radiata*) growing in pots containing prairie soil: left, nonmycorrhizal; right, mycorrhizal. Inset: A *Pinus* seedling showing the extensive fanlike development of its fungal partner. Also see Figure 23.20b, c.

Figure 23.24 Crown gall. Photograph of a crown gall tumor (arrow) on a tobacco plant caused by *Agrobacterium tumefaciens*. The disease usually does not kill the plant but may weaken it and make it more susceptible to drought and diseases.

Recognition and T-DNA Transfer

To initiate the tumorous state, *A. tumefaciens* cells attach to a wound site on the plant. Following attachment, the synthesis of cellulose microfibrils by the bacteria helps anchor them to the wound site, and bacterial aggregates form on the plant cell surface. This sets the stage for plasmid transfer from bacterium to plant. The general structure of the Ti plasmid is shown in **Figure 23.25**. Only the T-DNA is actually transferred to the plant. The T-DNA contains genes that induce tumorigenesis. The *vir* genes on the Ti plasmid encode proteins that are essential for T-DNA transfer. Transcription of *vir* genes is induced by metabolites synthesized by wounded plant tissues such as the phenolic compounds acetosyringone and ferulate. The transmissibility genes on the Ti plasmid (**Figure 23.25**) allow the plasmid to be transferred by conjugation (◀ Sections 9.8 and 9.9) from one bacterial cell to another.

The *vir* genes are the key to T-DNA transfer. The *virA* gene encodes a protein kinase (VirA) that interacts with inducer molecules and then phosphorylates the product of the *virG* gene (**Figure 23.26**). VirG is activated by phosphorylation and functions to activate other *vir* genes. The product of the *virD* gene (VirD) has endonuclease activity and nicks DNA in the Ti plasmid in a region adjacent to the T-DNA. The product of the *virE* gene is a DNA-binding protein that binds the single strand of T-DNA in the plant cell to protect it from destruction by nucleases. The *virB* operon encodes 11 different proteins that form a type IV secretion system (◀ Section 6.13) for single-strand T-DNA and protein transfer between bacterium and plant (**Figure 23.26**) and thus resembles bacterial conjugation. Laboratory studies of *A. tumefaciens* have shown that it can transfer T-DNA into many types of eukaryotic cells, including fungi, algae, protists, and even human cell lines.

Figure 23.25 Structure of the Ti plasmid of *Agrobacterium tumefaciens*. T-DNA is the region transferred to the plant. Arrows indicate the direction of transcription of each gene. The entire Ti plasmid is about 200 kilobase pairs (kbp) of DNA and the T-DNA is about 20 kbp.

Once inside the plant cell, T-DNA becomes inserted into the genome of the plant. Tumorigenesis (*onc*) genes on the Ti plasmid (**Figure 23.25**) encode enzymes for plant hormone production and at least one key enzyme of opine biosynthesis. Expression of these genes leads to tumor formation and opine production. The Ri plasmid responsible for hairy root disease also contains *onc* genes. However, in this case the genes confer increased auxin responsiveness on the plant, and this promotes overproduction of root tissue and the symptoms of the disease. The Ri plasmid also encodes several opine biosynthetic enzymes.

Genetic Engineering with the Ti Plasmid

From the standpoint of microbiology and plant pathology, crown gall disease and hairy root disease both require intimate interactions that lead to genetic exchange from bacterium to plant. In other words, tumor induction in these diseases is the result of a natural plant-transformation system. Because of this, recent interest in the Ti–crown gall system has shifted away from the disease itself toward applications of this natural genetic exchange process in plant genetic engineering and biotechnology.

Several modified Ti plasmids that lack disease genes but that can still transfer DNA to plants have been developed by genetic engineering. These have been used for the construction of genetically modified (transgenic) plants. Many transgenic plants have been constructed thus far, including crop plants carrying genes for resistance to herbicides, insect attack, and drought. We discuss the use of the Ti plasmid as a vector in plant biotechnology in Section 12.7.

Now we transition away from plants and look at some remarkable symbioses between bacteria and insects.

Check Your Understanding

- What are opines, and whom do they benefit?
- How do the *vir* genes differ from T-DNA in the Ti plasmid?
- How has an understanding of crown gall disease benefited plant agriculture?

Figure 23.26 Mechanism of transfer of T-DNA to the plant cell by *Agrobacterium tumefaciens*. (a) VirA activates VirG by phosphorylation, and VirG activates transcription of other *vir* genes. (b) VirD is an endonuclease that nicks the Ti plasmid, exposing the T-DNA. (c) VirB functions as a conjugation bridge between the *A. tumefaciens* cell and the plant cell, and VirE is a single-strand binding protein that assists in T-DNA transfer. Plant DNA polymerase produces the complementary strand to the transferred single strand of T-DNA.

III • Insects as Microbial Habitats

Mutualisms between microorganisms and insects are common, contributing nutritional advantages or protection from pathogens and predators. Bacterial symbionts can reside within specialized insect cells, associate with specialized surface structures, or colonize the insect gut.

Insects are the most abundant class of animals living today, with over 1 million species known. As many as 20% of all insects are thought to support symbiotic microbes in a mutually beneficial way. The symbioses contribute to the insects' ecological success by providing them either nutritional advantages or protection from parasites. Some symbionts are found on insects' outer surfaces or in their digestive tracts. *Endosymbionts* are intracellular bacteria and are typically localized at specialized organs within the insect.

23.7 Heritable Symbionts of Insects

How symbionts are transferred from one generation to the next determines how a mutualism functions and how stable it is. Microbial symbionts can either be acquired by a host from an environmental reservoir (*horizontal* transmission) or be transferred directly from the parent to the next generation (*heritable* or *vertical* transmission). The mode of symbiont transmission is related to the specificity and persistence of an association. In general, less specificity is associated with horizontal transmission. In this section we focus only on mutualisms in which the microbial symbiont has no free-living form; that is, the symbionts are transmitted in a vertical fashion.

Types of Heritable Symbionts

All known heritable microbial symbionts of insects lack a free-living replicative stage. Thus, they are *obligate* symbionts. However, although these bacteria require the host for replication, not all hosts are dependent upon the symbiont. Relative to host dependence, heritable symbionts are either *primary* or *secondary* symbionts. Primary symbionts are required for host reproduction. They are restricted to a specialized region called the **bacteriome** present in several insect groups; within the bacteriome the bacterial cells reside in specialized cells called **bacteriocytes**. Secondary symbionts are not required for host reproduction. Unlike primary symbionts,

secondary symbionts are not always present in every individual of a species and are not restricted to particular host tissues.

Secondary symbionts are broadly distributed among insect groups. Like pathogens, they invade different cell types and may live extracellularly within the insect's *hemolymph* (the fluid bathing the body cavity). In insects with bacteriomes, such as the cedar aphid (Figure 23.27a), secondary symbionts can invade the bacteriocytes, co-residing with or sometimes displacing the primary symbionts (Figure 23.27b). However, in order to persist in the insect host, the secondary symbiont must confer some advantage, such as a nutritional advantage or protection from environmental stresses such as heat. For example, whiteflies infected with the bacterium *Rickettsia* (◀ Section 16.1) produce offspring at about twice the rate of uninfected flies, and more offspring survive to adulthood. Secondary symbionts may also provide protection against invasion by pathogens or predators. A *Spiroplasma* species (◀ Section 16.9), which was first observed in *Drosophila neotestacea* in the 1980s, provides protection against a parasitic nematode worm. In most instances the basis for increased fitness or protection is unknown,

Figure 23.27 Primary and secondary symbionts of an aphid. (a) The cedar aphid *Cinara cedri*, a model organism for studies of symbioses. (b) Transmission electron micrograph of the bacteriome of *C. cedri* showing two bacteriocytes. Packed within each bacteriocyte are cells of *Buchnera aphidicola* (the primary symbiont) or *Serratia symbiotica*, the smaller, secondary symbiont. The nucleus of each bacteriocyte is identified. The bacteriocyte containing *Buchnera* cells is about 40 μm wide.

but in one case a toxin encoded by a lysogenic bacteriophage (◀ Section 5.6) carried by the symbiont is known to confer protection on the insect from infection by a parasitic wasp.

There are heritable parasitic symbionts that manipulate the host's reproductive system, increasing the frequency of female progeny (sex-ratio skewing, ◀ Figure 16.27). Because most heritable symbionts are transmitted maternally, the suppression of male progeny serves to expand the number of infected individuals and increase the rate of spread through an insect population. Since symbiont-conferred functions can spread rapidly within a population, acquisition of symbiont-encoded traits provides a mechanism for much more rapid adaptation than is possible through mutations in insect genes. *Rickettsia* infection of the whitefly population provides one example of how rapidly symbiont-conferred traits can spread through a population. Only 1% of whiteflies tested in the southwestern United States were infected with *Rickettsia* in 2000. In 2006, 97% of flies were infected.

An important applied benefit of improved basic understanding of insect symbionts is the increased use of symbionts in insect pest management and the control of vectorborne diseases, such as malaria and filariasis in humans (▶ Sections 34.5 and 34.7). For example, symbiotic *Wolbachia*, which are reproduction manipulators, are widely distributed among insect species (possibly infecting as many as 60–70% of all insect species). The sperm of *Wolbachia*-infected males can sterilize uninfected females. Although the mechanism for sterilization is not fully understood, the phenomenon is being tested as a means to suppress mosquito-borne human viral disease transmission (see Explore the Microbial World, “Combating Mosquito-Borne Viral Diseases with an Insect Symbiont”).

Nutritional Significance of Obligate Intracellular Symbionts of Insects

The association of bacteria and insects has allowed many insects to use food resources that are rich in some nutrients, but poor in others. To achieve adequate nutrition, some insects exploit the metabolic potential of their symbionts. For instance, aphids feed on the carbohydrate-rich but otherwise nutrient-poor sap of phloem vessels in plants. Early on it was suspected that obligate symbionts might benefit the insect by providing nutrients not provided by their primary diet, and this is now known to be true.

Molecular analyses have shown that most families of aphids harbor the bacterium *Buchnera* in their bacteriomes. The role of *Buchnera* in host nutrition was first indicated by experiments using defined diets to examine the nutrient requirements of aphids. Compared with infected controls, symbiont-free aphids required a diet containing all amino acids that are either lacking or rare in phloem sap. Subsequent genomic studies documented the presence in *Buchnera* of genes encoding the biosynthesis of nine amino acids missing from the sap. There are also examples of synergy between host and symbiont where the synthesis of certain amino acids becomes a joint venture. For example, *Buchnera* lacks the enzyme needed for the last step in leucine biosynthesis, but the necessary gene is present in the aphid's genome. Presumably, this enzyme is made by the aphid and participates in the leucine biosynthetic pathway along with the bacterial enzymes.

A secondary symbiont can also contribute to a joint venture. For example, the *Buchnera* symbiont of the cedar aphid is unable to supply tryptophan to the aphid. Two genes in the tryptophan

biosynthetic pathway are present in *Buchnera*, but the remaining genes for the pathway are located on the chromosome of a secondary endosymbiont (Figure 23.27). Thus, different parts of a required metabolic pathway can be encoded by different endosymbionts present in the same insect. The fungus-cultivating ants provide yet another example of a complex symbiosis that has formed between an insect and multiple microorganisms (as we review in the next section).

Mealybugs (*Planococcus citri*) present one of the most unusual examples of a partnership between two symbionts infecting the same insect. Mealybugs have two stable bacterial symbionts, “*Candidatus* Tremblaya princeps” (a *Betaproteobacterium*) and “*Candidatus* Moranella endobia” (a *Gammaproteobacterium*). (The term “*Candidatus*” means that these organisms are not yet in pure culture, ◀ Section 13.12, but we refer to them in the usual style below.) These symbionts cooperate in providing their host with essential amino acids missing in its diet, as is true for the symbionts of many sap-feeding insects. However, *Moranella* actually lives *inside of Tremblaya*, the only known example of a bacterium-within-a-bacterium symbiosis. The highly reduced *Tremblaya* genome has lost all genes for tRNA synthetases, an essential function supplied either by the host or by the *Moranella* residing within the cytoplasm of *Tremblaya*.

Genome Reduction and Gene Transfer Events

Common features of primary insect symbionts are extreme genome reduction (◀ Table 10.1), high adenine plus thymine content DNA, and accelerated rates of mutation. Genomes of most

TABLE 23.2 Genome features of some endosymbiotic Bacteria of animals^a

Host	Symbiont (genus)	Genome size (Mbp)	G + C (%)	Genes
Aphid	Heterotroph (<i>Buchnera</i>)	0.42–0.62	20–26	362–574
Tsetse fly	Heterotroph (<i>Wigglesworthia</i>)	0.70	22	617

Clam (<i>Calyptogena magnifica</i>)	Sulfur oxidizer (<i>Ruthia</i>)	1.2	34	1248
Tube worm (<i>Riftia pachytila</i>)	Sulfur oxidizer (unnamed)	3.3 ^b	NA	NA

^aAll listed symbionts are obligately associated with their hosts, with the exception of the symbiont of *Riftia*, which also has a free-living stage. For a comparison with the genomes of free-living Bacteria, see Table 10.1.

^bThe free-living sulfur-oxidizing bacterium *Thiomicrospira crunogena* has a genome significantly smaller (2.4 Mb) than this symbiont.

Combating Mosquito-Borne Viral Diseases with an Insect Symbiont

The global reemergence of mosquito-borne viral disease is correlated with rapid human population growth and urbanization, particularly in the tropics. Dengue (► Section 32.5) is now the world's most common mosquito-borne viral disease. In addition, major outbreaks of Zika virus (Figure 1a, b) have occurred in the South Pacific and the Americas, with infection in the Americas associated with congenital abnormalities. Urbanization has created greater opportunities for mosquito reproduction and transmission, and subtropical cities are the preferred habitat of the primary disease vector, *Aedes aegypti* (Figure 1c), which lives and breeds in building structures, urban waste, and pools of standing water.

With the tremendous resurgence of mosquito-borne disease, conventional mosquito control methods—eliminating breeding sites or applying insecticides—are no longer effective. In response to what is becoming a global crisis, novel technologies based on the rearing and releasing of large numbers of modified mosquitos into wild populations have been developed and tested in the field. The basic concept is to introduce mosquitoes modified in such a way that their mating with the native population yields nonviable offspring, thus reducing the size of the vector population. Some attempts have been made using sterilized males or genetically modified males that carry lethal genes. However, the most successful and cost-effective approach to date, and one that does not require genetic engineering or repeated releases of altered males, is the use of *Wolbachia*, a bacterium that naturally infects 40–60% of all insects.

Wolbachia is an insect endosymbiont that uses a mechanism called *cytoplasmic incompatibility* to promote its spread through insect populations. Infected females can mate successfully with both infected and uninfected

males, which enables the rapid spread of *Wolbachia* throughout a naive population. However, when infected males mate with uninfected females, the progeny are not viable, thus effectively sterilizing those females. Cytoplasmic incompatibility appears to be conferred by two incompatibility factors (*cifA* and *cifB*) encoded by a bacteriophage integrated

Later release studies in Australia showed that the introduction of *Wolbachia*-infected mosquitoes into an uninfected population can achieve an infection rate of over 90% for years, thus requiring far fewer mosquitoes and releases than other control methods.

The success of these early studies was the genesis for the World Mosquito Program.

Figure 1 Zika virus and its mosquito vector. (a) Transmission electron microscopic image of Zika viruses. Each virion is approximately 40 nm in diameter. (b) Zika virus structural model. (c) The *Aedes aegypti* mosquito, the principal vector for transmission of Zika fever, yellow fever, and dengue fever.

into the *Wolbachia* genome (a prophage, ◀ Section 5.6). Infection with *Wolbachia* also inhibits virus replication in the insect. In fact, mosquito transmission of dengue, Zika, and chikungunya viruses (► Section 32.5) is greatly reduced when *A. aegypti* mosquitoes are infected with *Wolbachia*.

The potential for effective pathogen control by *Wolbachia* was shown by the release of a large number of *Wolbachia*-infected male *Culex quinquefasciatus* mosquitoes in locations in Myanmar. This insect is the vector of the filarial nematode that causes elephantiasis (► Section 34.7), and the release effectively eliminated the local mosquito population.

This program is conducting large-scale release studies of *Wolbachia*-infected *A. aegypti* in Brazil, Colombia, and Indonesia that cover more than 2 million inhabitants in each study. These studies will yield the epidemiological evidence (disease tracking, Chapter 30) essential to fully document the efficacy of *Wolbachia* control of vectorborne diseases. However, as for all new technologies that affect natural systems, caution about unintended consequences is also essential. For example, whiteflies infected with the bacterium *Hamiltonella* (a symbiont related to enteric bacteria) are more likely than uninfected flies to transmit tomato yellow leaf curl virus to plants.

insect symbionts fall within a range from 0.12 to 0.80 megabase pairs (Mbp) and 16.5 to 33% G + C (Table 23.2). The 0.14-Mbp (140 kilobase-pair) genome of *Tremblaya princeps* is among the smallest genomes known for any cell. In contrast, the genomes of related free-living bacteria range from 2 to 8 Mbp with a base composition closer to 50% G + C. Two common types of spontaneous mutation, cytosine deamination and the oxidation of guanosine, if not repaired, change a GC pair to an AT pair (◀ Section 9.4). Symbionts with reduced genomes have fewer DNA repair enzymes (◀ Section 9.4), and this likely facilitates a shift over time to genomes of lower G + C content.

The streamlined genomes of insect symbionts have lost genes from most functional categories (Chapter 10) and tend to retain only genes required for host fitness and essential molecular processes, such as translation, replication, and transcription. Genome reduction implies that the symbionts are reliant on the host for many functions no longer encoded in the symbiont genome (◀ Section 10.3). For example, in many cases genes needed for the biosynthesis of cell wall components are missing, including lipid A and peptidoglycan, suggesting that the host supplies these functions or that the structures are not required to form stable cells within the bacteriocyte.

There is an interesting genomic contrast between primary symbionts and typical disease-causing bacteria (pathogens). While primary symbionts tend to lose genes encoding proteins required in *catabolic* pathways, pathogenic bacteria typically retain these, but lose genes for *anabolic* pathways. This reflects their differing relationships with their hosts; the insect symbiont provides the host with essential biosynthetic nutrients while the pathogen obtains important biosynthetic nutrients from the host.

Because genome sequences for a large number of insects and their symbionts are now appearing, microbiologists can begin to evaluate the frequency of gene transfer between them. Horizontal gene transfer is the movement of genetic information across normal mating barriers (Chapter 9 and 13). Although early research demonstrated that DNA of *Wolbachia* has been transferred to the nuclear genomes of their insect and nematode hosts, inspection of other insect mutualisms for which both host and symbiont genome sequences are available (e.g., aphid and body louse) indicate that DNA transfer is very rare. Even though transfer of genes between insect symbiont and host genomes appears to be very rare, as we will see in the next section, there can be extensive movement of genetic information between symbionts that associate with a specific insect host.

Check Your Understanding

- What are the consequences of symbiont genome reduction?
- How could it be determined if a symbiont and its host have experienced a long period of coevolution?

23.8 Defensive Symbioses

In addition to symbioses that provide nutritional benefits, other symbioses between insects and microbes provide the insect with a defense weapon. A widespread defensive strategy used by insects to deter pathogens and predators is the production of toxic and antimicrobial chemicals. The chemical deterrent is sometimes produced by the insect. For example, a toxic mix of hydroquinone and hydrogen peroxide is prepared in a specialized abdominal chamber of the bombardier beetle before being squirted at an approaching predator. However, in many more instances, the defensive chemical is the product of microorganisms symbiotically associated with the insect.

The Rove Beetle

An example of this defensive strategy can be found in the *Paederus* beetle (commonly called the rove beetle), which deters predators using the chemical *pederin* (Figure 23.28) synthesized by an endosymbiotic *Pseudomonas* species. This cytotoxic chemical (inhibiting mitosis in eukaryotes) accumulates in the insect's hemolymph and is deposited in its eggs, effectively deterring arthropod predation on the eggs. The beetle is better known in the tropics for causing severe dermatitis and blistering of the human skin if the insect is inadvertently crushed when brushed away, releasing the pederin-containing hemolymph.

Many such defensive symbioses are now recognized, protecting the insect from predation, parasitism, and microbial pathogens. Defensive chemicals are made by a wide variety of bacterial symbionts,

including members of the *Proteobacteria*, *Firmicutes*, and *Actinobacteria*. Some are intracellular, others reside within the gut, and others are associated with specialized anatomical structures on the insect exoskeleton. Comparative metagenomic analyses (◀ Sections 10.7 and 19.8) of symbiont gene content has shown that the array of defensive chemicals deployed by individual symbionts is primarily determined by horizontal gene transfer. Pathways for chemical synthesis commonly reside on plasmids and other mobile genetic elements (◀ Sections 6.2 and 9.11), such that even closely related symbionts can express very different defensive chemicals. Specific associations between insects and defensive symbionts are maintained by a variety of transmission mechanisms, including strictly vertical inheritance from the mother through the germ line and horizontal recruitment from the environment in each generation.

The Leafcutter Ants

The attine ants, more generally called leafcutter ants, are an example of an elaborate symbiotic association between multiple microbial species and insect. These ants have established an obligate mutualism with a fungus they cultivate, using small leaf fragments to feed the fungus. A close symbiotic relationship between ant and fungus was first indicated by the observation that one specific fungus was cultivated by each ant lineage. In addition to this close mutualistic relationship, the symbioses include four other microbial symbionts: a small fungus that is parasitic on the cultivated fungus, nitrogen-fixing bacteria (◀ Sections 3.12 and 15.9) associated with the cultivated fungus, an actinobacterium that antagonizes the parasitic fungus, and a black yeast that interferes with the actinobacterium.

The fungus is vertically transmitted between ant generations by colony-founding queens. The queen collects a pellet of fungus and, after mating, uses the fungus pellet to establish a new nest containing the cultivated fungus (Figure 23.29). Nitrogen-fixing *Klebsiella* and *Pantoea* species associated with the fungus enrich the nutritional quality of the garden by adding new nitrogen to the nitrogen-poor leaf growth substrate. The cultivated fungus is susceptible to a parasitic fungus of the genus *Escovopsis*, and to repel this parasite, the ant has formed another symbiotic association with an actinobacterium (genus *Pseudonocardia*) that appears as a “waxy bloom” growing on the cuticle of the ant (Figure 23.29b). These bacterial cells, housed in specialized cuticular modifications on the ant's body, secrete highly selective antimicrobial agents that inhibit the growth of *Escovopsis* but not the cultivated fungus.

Figure 23.28 Defensive chemical of insects. (a) The rove beetle. (b) The insect's bacterial symbiont produces large amounts of pederin, a highly cytotoxic defensive chemical that accumulates in the hemolymph of the beetle.

Figure 23.29 Leafcutter attine ants. (a) Queen and worker ants cultivating fungi. (b) Mutualism with the symbiont *Pseudonocardia* covers much of the exoskeleton of workers (white areas). The antifungal agent produced by the symbiont kills parasitic fungi but not the cultured fungi.

The *Pseudonocardia* cells likely receive nourishment from the ant in glandular secretions through pores localized in regions of cuticular modification. Comparative genomic sequencing has revealed good congruence between the phylogenies of the ants, fungal cultivars, *Escovopsis*, and *Pseudonocardia*, pointing to very specific interactions among microbes and ants in this complex symbiosis. The fourth and final microorganism identified in this symbiosis is a yeast that grows in the same cuticular regions colonized by the bacterium *Pseudonocardia*. This black-pigmented yeast interferes with chemical protection of the cultivated fungi by stealing nutrients from *Pseudonocardia*, thereby reducing its ability to suppress *Escovopsis* growth. The attine ant–microbial symbiosis is thus a complex maze of interactions between a macroorganism—the ant—and two groups of microbes, fungi and bacteria.

The Gut Microbiome of Bees

Bees and other animal pollinators provide vital ecosystem services. Thus, the loss of nearly 60% of honeybee colonies in the United States since 1947 is a major concern. Several factors are thought to contribute to this decline including fragmentation of habitats, pesticides, pollution, land use changes, and climate change. The decline of bee populations has also drawn attention to the importance of the bee gut microbiome for combating bee pathogens and environmental stressors.

The gut communities of bumblebees and honeybees (Figure 23.30) are surprisingly simple and consist of a core community of only five dominant and culturable bacterial species in adult worker bees. These include two gram-negative *Proteobacteria* (*Snodgrassella alvi* and *Gilliamella apicola*), two *Lactobacillus* species, and a *Bifidobacterium* species. *S. alvi* and *G. apicola* pack the lumen of the honeybee gut (Figure 23.30). Occasionally, up to four other species are present. Although different strains of each species in the core microbial community of the honeybee gut are closely related in 16S rRNA gene sequence, their genomes have diverged significantly through coevolution with bees over millions of years. As a result, strains have become host-specific. For example, *S. alvi* isolated from honeybees will not colonize bumblebees, and vice versa.

Metabolic interdependencies exist among microbes and the bee. For instance, *S. alvi* oxidizes the fermentation products of *G. apicola*, and *G. apicola* has genes for the degradation of pectin, a polysaccharide in

Figure 23.30 Scanning electron micrograph of honeybee gut microbiome. Five dominant bacterial species pack the lumen of the honeybee midgut as shown in the thin sectioned transmission electron micrograph.

the cell wall of pollen grains. Because bees do not produce pectinase and pollen is a key component of their diet, bee gut microbiota are essential for utilization of this important food source. Some bee gut microbes also carry genes for the utilization of uncommon sugars such as arabinose and raffinose that are indigestible and potentially toxic to the bee. This finely tuned microbiome plays a defensive role for the insect in that it inhibits invasive microorganisms through direct competition for space and resources and by stimulating the insect to produce antimicrobial peptides that target pathogenic bacteria.

Check Your Understanding

- How does the leafcutter ant prevent its cultivated fungus from being parasitized by another fungus?
- What is unusual about the diversity of the honeybee gut microbiome?
- How does the rove beetle use its *Pseudomonas* symbiont for protection?

23.9 Termites

Microorganisms are primarily responsible for the degradation of wood and cellulose in nature. However, the activities of free-living microbial species have been exploited by certain groups of insects that have established microbial symbioses in order to digest lignocellulosic materials. Like the rumen of many herbivorous animals (see Section 23.15), the insect gut provides a protective niche for microbial symbionts, and in return, the insect gains access to nutrients derived from an otherwise indigestible carbon source. Termites are among the most abundant representatives of this type of symbiotic alliance.

Termite Natural History and Biochemistry

Microbial symbionts in termites decompose the greater part of cellulose and hemicellulose in the plant material termites ingest. In contrast to the heritable insect symbionts discussed in Section 23.7, most termites do not harbor *intracellular* bacteria. Instead, the symbiotic bacteria are present in digestive organs (guts) as in the case of mammals. Termite diets include lignocellulosic plant materials (either intact or at various stages of decay), dung, and soil organic matter (humus). About two-thirds of the terrestrial environment supports one or more termite species, with the greatest representation in tropical and subtropical regions, where termites may constitute as much as 10% of all animal biomass and 95% of soil insect biomass.

Termites are categorized as higher or lower based on their phylogeny, and this classification correlates with different symbiotic strategies. The posterior alimentary tract of *higher* termites (family *Termitidae*, comprising about three-fourths of termite species) contains a dense and diverse community of mostly anaerobic bacteria, including cellulolytic species. In contrast, the *lower* termites harbor diverse populations of both anaerobic bacteria and cellulolytic protists. Bacteria of lower termites participate little or not at all in cellulose digestion; only the protists phagocytize and degrade the wood particles ingested by the termites.

The termite gut consists of a foregut (including the crop and muscular gizzard), a tubular midgut (site of secretion of digestive enzymes and absorption of soluble nutrients), and a relatively large hindgut of about 1 microliter volume (Figure 23.31). In lower termites, the hindgut consists primarily of a single chamber, the *paunch* (Figure 23.31a). The hindgut of higher termites is more complex, being divided into several compartments (Figure 23.31b). For both higher and lower termites, the hindgut harbors a dense and diverse microbial community and is a major site of nutrient absorption. Acetate and other organic acids are produced during microbial

fermentation of carbohydrate in the hindgut, and these products are primary carbon and energy sources for the termite (Figure 23.31c). High O_2 consumption by bacteria near the gut wall keeps the interior of the hindgut anoxic. However, microsensor measurements (◀ Section 19.9) have shown that O_2 can penetrate up to 200 μm into the gut before it is completely removed by microbial respiration (Figure 23.31c). Thus, this tiny gut compartment offers distinct microbial niches with respect to O_2 and can support diverse microbial activities.

Bacterial Diversity and Lignocellulose Digestion in Higher Termites

The microbial gut communities differ significantly in termites of different genera. Analysis of 16S rRNA gene sequences from hindgut contents of two genera of wood-eating higher termites (*Nasutitermes* and *Microcerotermes*) and one genus of a wood-eating lower termite (*Reticulitermes*) revealed a high diversity of microbial species from 12 phyla of *Bacteria*, but few *Archaea* (Figure 23.32). Spirochetes of the genus *Treponema* (◀ Section 15.17) dominated, with a lesser contribution from thus far uncultured organisms distantly related to the phylum *Fibrobacteres* (◀ Section 16.22), a group also present in the rumen (Figure 23.47).

Metagenomic analysis (◀ Sections 10.7 and 19.8) of the *Nasutitermes* hindgut microbial community has revealed bacterial genes encoding glycosyl hydrolases that hydrolyze cellulose and hemicelluloses. These metagenomic data clearly implicate spirochetes and *Fibrobacteres* in the digestion of lignocellulose, although the corresponding cellulolytic bacteria have not yet been isolated from the higher termites. The abundance of *Bacteroidetes* varies greatly between different species of higher termites, depending on their dietary preferences. In particular, *Bacteroidetes* are enriched in higher termites that digest wood with the help of a lignin-degrading basidiomycete fungus (*Termitomyces* spp.). As do the leafcutter ants

Figure 23.31 Termite gut anatomy and function. Gut architecture of lower (a) and higher (b) termites, showing the foregut, midgut, and differing complexity of the hindgut compartments. (c) Photo of workers, gut architecture, and biochemical activities of the lower termite *Coptotermes formosanus*. Microbial fermentation products, particularly acetate, are assimilated by the termite. Hydrogen produced by fermentation is consumed primarily by CO_2 -reducing acetogens, with a smaller amount going to hydrogenotrophic methanogens. Acetogenesis and methanogenesis are discussed in Sections 14.14 and 14.15 respectively. Syntrophic associations between protists and methanogens are discussed in Section 21.2 (◀ Figure 21.8).

Figure 23.32 Microbial composition of termite hindgut inferred from 16S rRNA sequences. The results are pooled analyses of 5075 sequences from amplified or metagenomic sequencing studies of three genera of wood-feeding higher termites, *Nasutitermes*, *Reticulitermes*, and *Microcerotermes*. The data provide a picture primarily of diversity, not relative abundance. Data assembled and analyzed by Nicolas Pinel.

(see Section 23.8), these termites cultivate fungi that they feed lignocellulosic plant litter. The termites feed on both the fungus and the partially digested wood. The *Bacteroidetes* in these termites encode many glycosyl hydrolases that assist in the breakdown of plant and fungal cell wall material. In addition to the cellulolytic activities of *Fibrobacteres* and *Spirochaetes* in termites specializing in direct consumption of wood, other cellulolytic species include *Ruminococcaceae*, the latter comprising a significant fraction of *Firmicutes* diversity in the termite gut (Figure 23.32). At every molting of an individual termite, gut symbionts are lost, yet there is good conservation of the gut community within each termite species. Stable horizontal transmission of gut symbionts likely occurs as a result of the intimate social behavior and close contact characteristic of termites.

Acetogenesis and Nitrogen Fixation in the Termite Gut

Genes encoding enzymes of the acetyl-CoA pathway (◀ Section 14.14) are highly represented in the spirochetes of the *Nasutitermes* hindgut, consistent with their function as the major CO₂-reducing acetogens. The termite gut microbial communities have long been recognized as important to host nitrogen metabolism, providing new fixed nitrogen (◀ Sections 3.12 and 15.9) and helping to conserve nitrogen by recycling excretory nitrogen back to the insect for biosynthesis. Consistent with this, metagenomic analyses have revealed that many bacteria, including *Fibrobacteres* and certain

spirochetes, contain genes encoding nitrogenase, the enzyme required to fix N₂.

From a simple energetic viewpoint, methanogenesis from H₂ and CO₂ is more favorable than acetogenesis from the same substrates (−34 kJ/mol of H₂ versus −26 kJ/mol of H₂, respectively), and thus methanogens should have a competitive advantage in all habitats in which the two processes compete (◀ Sections 14.14–14.15). However, in termites they do not. There are at least two reasons for this. First, unlike methanogens, acetogens are able to use other substrates such as sugars or methyl groups from lignocellulose degradation as electron donors for energy metabolism. Second, termite acetogens (which seem to consist mostly of spirochetes) can for some reason better colonize the H₂-rich termite gut center, whereas methanogens are largely restricted to the gut wall. On the gut wall, methanogens are located downstream of the H₂ gradient and thus receive only a fraction of the H₂ flux. In addition, the wall likely contains higher O₂ tensions, which may negatively affect the physiology of methanogens. So, despite the fact that termites are methanogenic, producing up to 150 teragrams of CH₄ per year on a global basis (1 teragram = 10¹² grams), carbon and electron flow in the termite gut favor acetogenesis in this interesting anoxic microbial habitat.

IV • Other Invertebrates as Microbial Habitats

Microbial symbionts of invertebrates perform different behavioral and nutritional functions. Some symbionts provide a light source to their host while others absorb light or consume inorganic chemicals to feed the animal. In some cases the invertebrate uses the symbiont as an offensive weapon, producing toxic compounds to kill its prey.

Thus far in this chapter we have discussed how certain macroorganisms that live in terrestrial environments provide habitats for microbial symbionts. We now consider some additional symbioses occurring in both terrestrial and aquatic environments. We begin in the marine environment as microbial symbioses with marine animals, especially with invertebrates, are common. By finding habitats in marine invertebrates, microorganisms establish a safe residence in a nutritionally rich environment.

23.10 Bioluminescent Symbionts and the Squid Symbiosis

Some bacteria can emit light, and this capacity has been exploited by several marine invertebrates. The light organ of the Hawaiian bobtail squid has become an important model system for such

symbioses, especially for resolving the complex communication between microorganism and animal required for establishing a specific and stable symbiosis.

Key Bioluminescent Genera and Biochemistry of Bioluminescence

Several species of bacteria among the genera *Vibrio*, *Aliivibrio*, *Photobacterium*, *Shewanella*, and *Photorhabdus* (all *Gamma*proteobacteria, ◀ Section 16.4) can emit light, a process called **bioluminescence** (Figure 23.33). Most bioluminescent bacteria inhabit the marine environment, and some species colonize specialized *light organs* of certain marine fishes and squids, producing light that the animal uses for signaling, avoiding predators, and attracting prey (Figure 23.33c–f). When living symbiotically in light organs of fish and squids, or saprophytically, for example on the skin of a dead fish, or parasitically in the body of a crustacean, luminous bacteria can be recognized by the light they produce.

Mechanism and Ecology of Bioluminescence

Although *Photobacterium*, *Aliivibrio*, and *Vibrio* isolates are facultative aerobes, they are bioluminescent only when O₂ is present. Luminescence in bacteria requires the genes *luxCDABE* (◀ Section 7.7) and is catalyzed by the enzyme *luciferase*, which uses O₂, a long-chain aliphatic aldehyde (RCHO) such as tetradecanal, and reduced flavin mononucleotide (FMNH₂) as substrates:

The light-generating system constitutes a metabolic route for shunting electrons from FMNH₂ to O₂ directly, without employing other electron carriers such as quinones and cytochromes.

Luminescence in many luminous bacteria only occurs at high population density. The enzyme luciferase and other proteins of the bacterial luminescence system exhibit a population density–responsive induction, called **autoinduction**, in which transcription of the *luxCDABE* genes is controlled by a regulatory protein, LuxR, and an inducer molecule, acyl homoserine lactone (AHL, ◀ Section 7.7 and Figure 7.18). During growth, cells produce AHL, which can rapidly cross the cytoplasmic membrane in either direction, diffusing in and out of cells. Under conditions in which a high local population density of cells of a given species is attained, as in a test tube, a colony on a plate, or in the light organ of a fish or squid, AHL accumulates. Only when it reaches a certain concentration in the cell is AHL bound by LuxR, forming a complex that activates transcription of *luxCDABE*; cells then become luminous (Figure 23.33b, ◀ Figure 1.3).

This gene regulatory mechanism is called *quorum sensing* because of the population density–dependent nature of the phenomenon (◀ Section 7.7). The strategy of quorum-sensing induction of luminescence ensures that luminescence develops only when population densities are high enough to allow the light produced to be visible to animals. The bacterial light can then attract animals to feed on the luminous material, thereby bringing the bacteria into the animal's nutrient-rich gut for further growth. Alternatively, the luminous material may function as a light source in symbiotic light organ associations (Figure 23.33c, d). Quorum sensing is a form of

Figure 23.33 Bioluminescent bacteria and their role as light organ symbionts in the flashlight fish. (a) Two Petri plates of luminous bacteria photographed by their own light. Note the different colors. Left, *Aliivibrio fischeri* strain MJ-1, blue light, and right, strain Y-1, green light. (b) Colonies of *Photobacterium phosphoreum* photographed by their own light (◀ Figure 1.3). (c) The flashlight fish *Photoblepharon palpebratus*; the bright area is the light organ containing bioluminescent bacteria. (d) Same fish photographed by its own light. regulation that has been detected in many different bacteria, controlling activities such as the production of extracellular enzymes and expression of virulence factors for which a high population density is beneficial if the bacteria are to have a biological effect.

The Squid–*Aliivibrio* System as a Model Symbiosis

The Hawaiian bobtail squid, *Euprymna scolopes*, is a small marine invertebrate (Figure 23.34a) that harbors a large population of the bioluminescent bacterium *Aliivibrio fischeri* (Figure 23.33a) in a light organ located on its ventral side (Figure 23.34b and see Figure 23.35). Squid and bacterium are partners in a mutualism. The bacteria emit light that resembles moonlight penetrating marine waters, and this is thought to camouflage the squid from predators that strike from beneath. Several other species of *Euprymna* inhabit marine waters near Japan and Australia and in the Mediterranean, and these contain *Aliivibrio* symbionts as well.

Many features of the *E. scolopes*–*A. fischeri* symbiosis have made it an important model for studies of animal–bacterial symbioses. These include the facts that the animals can be maintained in the laboratory and that only a single bacterial species is in the symbiosis in contrast to the large number of species in symbioses such as those of the termite (Figure 23.32) or the mammalian large intestine (Chapter 24). In addition, the symbiosis is not an essential one; both the squid and its bacterial partner can survive apart from each other in the laboratory. This allows juvenile squid to be grown without bacterial symbionts and then experimentally colonized. Experiments can be done to study specificity in the symbiosis, the number of bacterial cells needed to initiate an infection, the capacity of genetically defined mutants of *A. fischeri* to initiate infection of the squid, and many other aspects of the relationship. Moreover, because the genome of *A. fischeri* has been sequenced, microbial genomics may be employed to help interpret experimental results.

Establishing the Squid–*Aliivibrio* Symbiosis

Juvenile squid just hatched from eggs do not contain cells of *A. fischeri*. Thus, transmission of bacterial cells to juvenile squid is a horizontal (environmental) rather than a vertical (parent to offspring) event. Almost immediately after juveniles emerge from eggs, cells of *A. fischeri* in surrounding seawater begin to colonize them,

entering through ciliated ducts that end in the immature light organ. Amazingly, the light organ becomes colonized *specifically* with *A. fischeri* and not with any of the many other species of gram-negative bacteria present in the seawater. Even if large numbers of other species of bioluminescent bacteria are offered to juvenile squid along with low numbers of *A. fischeri*, only *A. fischeri* establishes residence in the light organ. This implies that the animal recognizes and accepts *A. fischeri* cells and excludes those of other species.

Initial colonization of the squid light organ by *Aliivibrio* has three basic stages: (1) first contact, exclusion of unwanted microbes, and symbiont enrichment and aggregation, (2) chemotactic migration of the symbionts to the light organ colonization pore, and (3) migration of the symbionts into the crypts of the light organ interior, followed by loss of flagella and cell division (Figure 23.35). Contact of the squid with any bacterial cells triggers recognition in a very general way. Upon contact with peptidoglycan (a component of the cell wall of *Bacteria*, ◀ Section 2.3), the ciliated surface of the young squid's immature light organ secretes an acidic mucus, trapping the bacteria on its developing light organ. The mucus is the first layer of specificity in the symbiosis, as it makes gram-negative but not gram-positive bacteria aggregate (Figure 23.35a).

Within the aggregates, *A. fischeri* outcompetes the other gram-negative bacteria to form a monoculture within 2 h of a juvenile's hatching from an egg. Specific colonization is aided by the chemical environment generated by squid, including production of antimicrobial peptides and the gas nitric oxide (NO, see below), which helps the aggregating *A. fischeri* compete against attempted colonization by other gram-negative bacteria and facilitates their migration into the light organ (Figure 23.35b). The aggregated cells respond chemotactically to a gradient of specific sugars released from colonization pores (Figure 23.35c), migrating up this chemical gradient and into the pores. From there the cells continue their migration into the crypts of the light organ (Figure 23.35d). At this point, another critical selection process takes place. Only a single *Aliivibrio* cell enters and grows in each crypt of the light organ; when inside, it sheds its flagella and divides to form a dense population (Figures 23.35d and 23.34b). These initial colonization events trigger developmental events in the squid that lead to maturation of the light organ (Figure 23.35e). Each light organ in a mature *E. scolopes* contains between 10^8 and 10^9 *A. fischeri* cells.

(a) *Aliivibrio fischeri* (green fluorescence) aggregates on the mucus-covered (blue) immature light organ surface of *Euprymna scolopes* (aggregates are approximately 100 μm long). (b, c) Chemotactic migration of *A. fischeri* cells (red fluorescence) along the ciliated surface (green) of the light organ, following a gradient of sugars released from the colonization pores. (d) *A. fischeri* cells migrate from the pore through the light organ along the direction of the white arrows to colonize the crypts (yellow arrows). Host nuclei are stained blue and *A. fischeri* cells fluoresce red or green (each cell aggregate is approximately 40 μm wide). (e) Following colonization of the light organs, the symbionts trigger the loss of the ciliated lobe-like appendages that are no longer needed for collection of *A. fischeri* cells from seawater. *A. fischeri* cells were genetically modified to express the green fluorescent protein or red fluorescent protein (◀ Section 19.4).

Colonization by *A. fischeri* in the squid is assisted by nitric oxide (NO). Nitric oxide is a well-known defense response of animal cells to attack by bacterial pathogens; the gas is a strong oxidant and causes sufficient oxidative damage to kill bacterial cells (▶ Section 26.7). Nitric oxide produced by the squid is incorporated into the aggregates in the mucus and is present in the light organ itself. As *A. fischeri* colonizes the light organ, NO levels diminish rapidly. It appears that cells of *A. fischeri* can tolerate exposure to NO and actually consume it through the activity of NO-inactivating enzymes. The inability of other gram-negative bacteria in the aggregates to detoxify NO helps explain the sudden enrichment of *A. fischeri* in the ducts even before the actual colonization of the light organ. Then, after establishment, continued production of NO in the light organ prevents colonization by other bacterial species.

Propagating the Symbiosis

The squid matures into an adult in about 2 months and then lives a strictly nocturnal existence in which it feeds mostly on small

crustaceans. During the day, the animal buries itself and remains quiescent in the sand. Each morning at dawn the squid nearly empties its light organ of *A. fischeri* cells and begins to grow a new population of the bacterium; by midafternoon, the structure contains the dense populations of *A. fischeri* cells required for the production of visible light. The actual emission of light requires a certain density of cells and is controlled by quorum sensing (◀ Section 7.7). This daily growth and expulsion of bacterial cells is thought to be a mechanism for seeding the environment with cells of the bacterial symbionts; this increases the chances that the next generation of juvenile squid will be colonized and the symbiosis maintained.

A. fischeri clearly benefits from the squid symbiosis. The bacterium grows much faster in the light organ than in the open ocean, presumably because it is supplied with nutrients by the squid and is in a protected environment where it can avoid predation. *A. fischeri* is not a particularly abundant marine bacterium. Thus, the bacterium benefits by having an alternative habitat to seawater in

which rapid growth and dense populations are possible. Daily expulsion of *A. fischeri* cells from the light organ increases the bacterium's numbers in the microbial community. Hence, the symbiotic relationship of the bacterium with the squid helps maintain larger populations of *A. fischeri* than if the organism were strictly free-living. Because the competitive success of a microbial species is to some degree a function of population size (◀ Section 20.1), this boost in cell numbers may confer an important ecological advantage on *A. fischeri* in its marine habitat.

Check Your Understanding

- What substrates and enzyme are required for an organism such as *Aliivibrio* to emit visible light?
- What is quorum sensing, and how does it control bioluminescence?
- What features of the squid–*Aliivibrio* symbiosis make it an ideal model for studying animal–bacterial symbioses?

23.11 Marine Invertebrates at Hydrothermal Vents and Cold Seeps

Diverse invertebrate communities develop near undersea hot springs called *hydrothermal vents*. We covered the geochemistry and microbiology of hydrothermal vents and cold seeps of natural gas in Sections 20.16 and 21.1. Here we focus on hydrothermal vent invertebrates and their microbial symbionts.

Macroinvertebrates, including tube worms over 2 m in length and large clams and mussels, are present near these vents (Figure 23.36). Photosynthesis cannot support these invertebrate communities because they exist below the photic zone. However, hydrothermal fluids contain large amounts of reduced inorganic materials, including H_2S , Mn^{2+} , H_2 , and CO (carbon monoxide), and some vents contain high levels of ammonium (NH_4^+) instead of H_2S ; all of these are good electron donors for chemolithotrophs—*Bacteria* and *Archaea* that use inorganic compounds as electron donors and fix CO_2 as their carbon source (Chapter 14). Thus, hydrothermal vent invertebrates thrive in permanent darkness because they receive nourishment through a symbiotic association with these autotrophic bacteria.

Tube Worms, Mussels, and Giant Clams

Hydrothermal vent-associated animals either feed directly on cells of free-living chemolithotrophs or have formed tight symbiotic associations with them. Mutualistic chemolithotrophs are either tightly attached to the animal surface (that is, as *epibionts*, Section 23.2 and Figures 23.5 and 23.29b) or actually live within the animal tissues, supplying organic compounds to the animals in exchange for a safe residence and ready access to the electron donors needed for their energy metabolism. For example, the 2-m-long tube worms (Figure 23.36a) lack a mouth, gut, and anus, but contain an organ consisting primarily of spongy tissue called the *trophosome*. This structure, which constitutes half the worm's weight, is filled with sulfur granules and large populations of spherical sulfur-oxidizing bacteria (Figure 23.37).

Bacterial cells taken from trophosome tissue show activity of enzymes of the Calvin cycle, a major pathway for autotrophy (◀ Section 3.12), but interestingly, they also contain enzymes of the reverse citric acid cycle, a second autotrophic pathway (◀ Section 14.2). In addition, they contain the sulfur-oxidizing enzymes necessary to obtain energy from reduced sulfur compounds (◀ Sections 14.7 and 15.12). The tube worms are thus nourished by organic compounds produced from CO_2 and secreted by the sulfur chemolithotrophs.

Along with tube worms, giant clams and mussels (Figure 23.36b) are also common near hydrothermal vents, and sulfur-oxidizing bacterial symbionts have been found in the gill tissues of these animals. Phylogenetic analyses have shown that each individual animal harbors one or more different strains of bacterial symbiont and that a variety of species of bacterial symbionts inhabit different species of vent animal. With the exception of the bacterial symbiont of *Riftia* (tube worms), which also has a free-living stage (Table 23.2), none of the bacterial symbionts of hydrothermal vent animals have yet been obtained in laboratory culture, even though they are fairly closely related to free-living sulfur chemolithotrophs (◀ Sections 14.7 and 15.12).

The red plume of the tube worm (Figure 23.36a) is rich in blood vessels and is used to trap and transport inorganic substrates to the bacterial symbionts. Tube worms contain unusual hemoglobins that bind H_2S and O_2 ; these are then transported to the trophosome where they are released to the bacterial symbionts. The CO_2 content of tube-worm blood is also high, about 25 mM, and presumably this is released in the trophosome as a carbon source for the symbionts. In addition, stable isotope analyses (◀ Section 19.10) of elemental sulfur from the trophosome have shown that its $^{34}\text{S}/^{32}\text{S}$ composition is the same as that of the sulfide emitted from the vent. This ratio is distinct from that of seawater sulfate and is solid evidence that geothermal sulfide is actually entering the worm in large amounts.

Other Invertebrate Symbionts

Other marine invertebrates have coevolved bacterial symbioses that supply their nutrition as well (Table 23.3). For example, methanotrophic (CH_4 -consuming) symbionts are present in giant clams that live near cold seeps of natural gas at relatively shallow depths in the Gulf of Mexico. Although not autotrophs (CH_4 is an organic compound), the methanotrophs do provide nutrition to the clams; the methanotrophs use CH_4 as their electron donor and carbon source and secrete organic carbon to the clams.

Molecular hydrogen (H_2) is used as an electron donor by the mussel *Bathymodiolus puteoserpentis*, the most abundant macrofauna in vent fields associated with the peridotite-hosted vent systems of the Mid-Atlantic Ridge (◀ Section 20.16 and Figure 20.45). These systems release high levels of H_2 and CH_4 , with H_2 concentrations as high as 19 mM. This mussel was previously shown to live in a dual symbiosis with methane-oxidizing bacteria and chemolithotrophic sulfur-oxidizing bacteria localized to the gill tissue. Remarkably, the sulfur-oxidizing symbiont of *B. puteoserpentis* also has the capacity to use H_2 as an electron donor, making this mussel one of the most metabolically versatile of vent macrofauna.

Genomics and Hydrothermal Vent Symbioses

Genome sequencing is revealing additional features of the metabolic interaction and coevolution of marine invertebrates and their bacterial symbionts. The genome sequence of the gill endosymbiont of the giant vent clam *Calyptogena magnifica* provides direct evidence for autotrophy by way of the Calvin cycle because the genome encodes the key enzymes of the cycle, ribulose biphosphate carboxylase and phosphoribulokinase (◀ Section 3.12). This genome also contains genes encoding key sulfur-oxidation processes and genes encoding the biosynthesis of most vitamins and cofactors and all 20 amino acids needed to support the host. However, because few substrate-specific transporters are encoded by the symbiont genome—proteins necessary to secrete organic compounds to the host—it is likely that the clam actually digests symbiont cells for nutrition, as do mussels.

TABLE 23.3 Marine animals with chemolithotrophic or methanotrophic endosymbiotic <i>Bacteria</i>			
Host phylum (genus or order)	Common name	Habitat	Symbiont metabolic type
Porifera (Demospongiae)	Sponge	Seeps	Methanotrophs
Platyhelminthes (Catenulida)	Flatworm	Shallow water	Sulfur chemolithotrophs
Nematoda (Monhysterida)	Mouthless nematode	Shallow water	Sulfur chemolithotrophs
Mollusca (Solemya, Lucina)	Clam	Vents, seeps, shallow water	Sulfur chemolithotrophs
Mollusca (Calyptogena)	Clam	Vents, seeps, whale falls ^a	Sulfur chemolithotrophs
Mollusca (Bathymodiolus)	Mussel	Vents, seeps, whale and wood falls ^a	Sulfur and H_2 chemolithotrophs, methanotrophs
Mollusca (Alviniconcha)	Snail	Vents	Sulfur chemolithotrophs
Annelida (Riftia)	Tube worm	Vents, seeps, whale and wood falls ^a	Sulfur chemolithotrophs

^aWhale and wood falls are sunken whale carcasses and wood, respectively.

Like the obligate symbionts of insects, most symbionts of marine invertebrates have small genomes (Table 23.2), indicating reduced function and an obligate association with their host. The bacterial symbiont of the giant tube worm *Riftia pachyptila* is an exception, having a genome larger than some free-living sulfur-oxidizing chemolithotrophs (Table 23.2). The *R. pachyptila* symbiont is acquired by uninfected juvenile animals from the environment (horizontal transmission), and its larger genome is likely important for survival in the free-living state. For more on the tube worm–microbe symbiosis, see Explore the Microbial World “Pattern Recognition Receptors of Hydrothermal Vent Tube Worms Facilitate Endosymbiosis” in Chapter 26.

Check Your Understanding

- How do giant tube worms receive their nutrition?
- What are the similarities of the obligate symbioses of insects and hydrothermal vent invertebrates?
- Why might some marine invertebrates contain large genomes and others small genomes?

23.12 Entomopathogenic Nematodes

Two families of nematodes—the *Heterorhabditidae* and *Steinernematidae*—are obligate pathogens of insects and together constitute a group of entomopathogenic (insect-killing) invertebrates that have a wide range of insect hosts. The basis for their insect lethality is a specific association between the nematode and its bacterial symbionts, which produce a variety of insecticidal compounds. However, unlike the insects making defensive use of symbiont products that we explored in Section 23.8, the nematode uses the compounds produced by its bacterial symbiont to kill insect prey.

Figure 23.38 Nematode–*Xenorhabdus* life cycle. (a) In the presence of nutrients released in the infected insect, the nematodes develop through four juvenile stages (J1–J4), molting between stages, to egg-laying adults. When nutrients become limiting, the nematodes develop into an alternative nonfeeding J3 stage (known as the infective juvenile) that closes off most of its intestine and forms a receptacle in the gut where symbiotic bacteria localize. The infective J3 stage nematodes are then released into the environment to infect other insects. (b) *Xenorhabdus* localized to the bacterial receptacle of the infective juvenile. (c) Bacteria-filled receptacle imaged by differential interference contrast microscopy. *Xenorhabdus* colonizing the nematodes shown in a and b were genetically engineered to express the green fluorescent protein (◀ Sections 8.1 and 19.4) for imaging by fluorescence microscopy. Nematodes are approximately 50 μm in diameter.

Specificity of Entomopathogenic Nematodes for Their Symbionts and Insect Hosts

Species of the gram-negative bacteria *Photorhabdus* and *Xenorhabdus* are the primary bacterial symbionts of the entomopathogenic nematodes. Comparative 16S rRNA sequence analysis (◀ Section 13.11) has shown a high specificity of association between bacterial and nematode species. Species of *Photorhabdus* specifically associate with *Heterorhabditidae*, whereas *Xenorhabdus* species selectively associate with *Steinernematidae*. Each *Steinernema* species is thought to associate specifically with only one *Xenorhabdus* species. However, a single *Xenorhabdus* species may be associated with more than one nematode species. In turn, the nematodes comprising these two families can be separated into several phylogenetic groups that correspond to the phylogenetic relationships of their insect hosts. Together these data point to a history of coevolution between nematodes and their bacterial symbionts that has resulted in the various entomopathogenic nematodes having different insect host specificities.

The Nematode Life Cycle and Lethality

All entomopathogenic nematodes have a similar life cycle in which only one stage, the nonfeeding third-stage infective juvenile, survives outside the host (Figure 23.38). The long association between nematode and bacterial symbiont has also resulted in modification of the anterior part of the infective juvenile nematode's intestine. This region forms a discrete chamber in the infective juvenile called the *bacterial receptacle* (Figure 23.38b, c). This vessel becomes filled with bacteria by growth of the symbiont during maturation of the infective

juvenile, protecting the symbiont for the next infective cycle.

When the infective juvenile encounters an appropriate insect host, it invades the insect's hemocoel (the body cavity containing the bloodlike hemolymph of the insect's circulatory system) through a natural opening such as the mouth or anus. The bacteria are then released from the bacterial receptacle into the hemolymph and grow rapidly. They are able to thwart the insect's natural immune system in part by producing a variety of hemolysins, toxins, and digestive enzymes (e.g., proteases, lipases, chitinases) that promote the release of nutrients from host tissues. The bacterial symbionts also produce antibiotics to inhibit competitive colonization by other microbes. Both the multiplying bacteria and digested host tissues nourish the multiplying nematodes, and this results in a slow insect death, taking anywhere from 1 to 22 days. As the

nutrients in the host become depleted, the adult nematodes produce new infective nonfeeding juveniles that are adapted to withstand the outside environment (Figure 23.38a), and the life cycle repeats.

Practical Applications of Entomopathogenic Nematodes

Entomopathogenic nematodes have been extensively studied as bio-control agents, providing an alternative to broad-spectrum chemical pesticides in the control of insect pests. In addition to alleviating possible human health effects of chemical pesticides, biologically based insect control strategies can be highly specific, targeting the pest species but not other insects. This specificity helps maintain the natural insect biodiversity in environments that require pest species management, most commonly in agricultural settings. Apart from their application in pest management, this symbiosis has also provided a powerful model system for developing a detailed understanding of the evolution, physiology, and genetics of beneficial host–microbe interactions.

Check Your Understanding

- What evidence suggest that the nematodes and their bacterial symbionts have coevolved?
- What prevents other bacteria from colonizing the dead insect and competing with the nematode and *Xenorhabdus* for nutrients?

23.13 Reef-Building Corals

Coral reef ecosystems are the products of mutualistic associations between microscopic phototrophs and simple marine animals. The

extensive ecosystems associated with the worldwide distribution of these mutualisms support thousands of species of fish and marine invertebrates.

Phototrophic Symbioses with Animals

Some animals establish mutualistic associations with algae or cyanobacteria (Table 23.4). The animals in most of these associations are in phyla that display very simple body plans, for example, the *Porifera* (sponges) and *Cnidaria* (corals, sea anemones, and hydroids). These mutualistic animal–bacterial associations live in clear tropical waters where nutrients for the animals are scarce, and the animal body typically has a large surface area relative to its volume and is thus well suited for capturing light.

There are only a few instances of algae forming associations with more complex animals, such as those in the phyla *Platyhelminthes* (flatworms), *Mollusca* (snails and clams), and *Urochordata* (sea squirts). In these cases, either the animal has a suitable surface-to-volume ratio or has evolved specific light-gathering surfaces. The unicellular phototrophic symbionts are phylogenetically diverse and include cyanobacteria (◀ Section 15.3), and red and green algae, diatoms, and dinoflagellates (Chapter 18). The most common symbionts are green algae (*Chlorella*, associating with sponges and freshwater hydras), cyanobacteria (associating with marine sponges), and species of the dinoflagellate genus *Symbiodinium* (◀ Section 18.4; Figure 23.39). We focus here on the symbiotic association between the dinoflagellate *Symbiodinium* and the stony coral cnidarians (see also MicrobiologyNow on page 780).

The Staghorn Coral Symbiosis

The staghorn coral is representative of the mutualism between the stony corals (phylum *Cnidaria*) and *Symbiodinium*. Stony corals are among the most spectacular and ecologically significant animal–phototroph associations. Each coral is a colony of genetically identical polyps (Figure 23.40) that together build the calcium carbonate structure. The *Symbiodinium* symbiont is distributed throughout the coral skeleton in the coral tissue (Figure 23.40c). Together the corals and dinoflagellates form the trophic and structural foundation of the coral reef ecosystem.

The stony corals possess a simple two-tissue-layer body plan (ectoderm and gastroderm) and harbor their dinoflagellate symbiont

TABLE 23.4 Symbioses between animals and phototrophic symbionts		
Host	Common name	Symbionts ^a
<i>Porifera</i>	Sponge	Cyanobacteria, <i>Chlorella</i> , <i>Symbiodinium</i>

^aCyanobacteria are *Bacteria*; all others are eukaryotic phototrophs.

intracellularly in membrane-bound vesicles called *symbiosomes* within cells of the inner (gastrodermal) tissue layer (Figure 23.39c). The coral symbiosomes are analogous to the bacteroid-filled vesicles that develop in plant cells of the legume root nodules (Section 23.4). The coral skeleton is an extremely efficient light-gathering structure that greatly enhances light harvesting by *Symbiodinium* cells to maintain the symbiosis.

Transmission, Specificity, and Benefits of the *Symbiodinium*–Coral Association

Reef-building corals reproduce sexually by releasing gametes into the seawater. A male and a female gamete fuse to form a free-swimming larva that later settles on a surface, where it may initiate a new coral colony. Algal symbionts can be present in the egg before it is released from the parent (vertical transmission), or acquired from the environment by juvenile corals (horizontal transmission). A developing coral that ingests dinoflagellates digests all of them except the particular strain of *Symbiodinium* of its mutualism. After establishing an association, the coral controls the growth of *Symbiodinium* via chemical signaling and, following each cell division, each *Symbiodinium* daughter cell is allocated to a new symbiosome.

Both partners in the stony coral–dinoflagellate mutualism have evolved adaptations for nutritional exchange. The dinoflagellates donate most of their photosynthetically fixed carbon (in the form of small molecules such as sugars, glycerol, and amino acids) to

Figure 23.39 *Symbiodinium* symbiont of marine invertebrates. (a) Thin-section micrograph of *Symbiodinium* in the mantle tissue of a giant clam. (b) *Symbiodinium* cells recovered from a soft coral. (c) Transmission electron micrograph of a *Symbiodinium* cell within a vacuole of a cell of the stony coral *Ctenactis echinata*. The *Symbiodinium* cell is about 10 μm in diameter.

Figure 23.40 Staghorn coral. (a) Photograph of a large, branched colony of reef-building staghorn coral (11 cm at its widest). (b) Close-up of a coral branch. Each polyp (arrows) is around half a millimeter in size. The brown bands are caused by the photosynthetic symbionts living within the coral tissue. (c) Fluorescence microscopy of a single polyp on a branch of the colony reveals symbionts (red autofluorescence from chlorophyll) living inside the polyp's tentacles, and in bands along its sides.

the cnidarian in exchange for inorganic nitrogen, phosphorus, and inorganic carbon from the host. Moreover, in addition to providing protection and inorganic nutrients, the calcium carbonate skeleton of corals is one of the most efficient collectors of solar radiation in nature, amplifying the incident light field for the symbionts by as much as fivefold; this benefits the symbiont in carrying out photosynthesis under a light-absorbing water column. This mutualism between animal and phototroph has allowed coral reefs to thrive in large expanses of nutrient-poor ocean waters.

Coral Bleaching—The Risk of Harboring a Phototrophic Symbiont in a Changing World

Many of the extensive coral reef systems in the oceans are threatened with extinction, primarily as a consequence of human activities. Ongoing loss of these beautiful and productive ecosystems is thought to be the result of elevated atmospheric CO₂; namely, increased sea

surface temperature, rising sea levels, and ocean acidification (◀ Sections 21.7 and 21.9). Coastal development also threatens reef systems, contributing to pollution from sewage discharge, eutrophication from nutrient runoff, and overfishing. These environmental changes are contributing to high mortality through disease, loss of coral structure from reduced calcification caused by acidification, and bleaching. Healthy corals harbor millions of cells of *Symbiodinium* per square centimeter of tissue. Coral bleaching is the loss of color from host tissues caused by the lysis or expulsion of these pigmented symbionts, revealing the underlying white limestone skeleton (Figure 23.41).

Coral reefs live close to their optimum temperature, and it is the synergistic effect of increased sea surface temperature and irradiance that causes massive bleaching. Elevated temperature and high irradiance impair the photosynthetic apparatus of the dinoflagellates, resulting in the production of reactive oxygen species (for example, singlet oxygen and superoxide, ◀ Section 4.16) that cause damage to both host and symbiont. Bleaching is thought to be caused by a protective immune response of the host that destroys compromised symbionts. Increases in sea surface temperatures as small as 0.5–1.5°C above the local maximum, if sustained for as little as several weeks, can induce rapid coral bleaching. Such thermal stress has resulted in bleaching of huge expanses of coral reefs, providing additional and highly visible evidence that climate change is upon us and that microbially based ecosystems are responding.

(a)

(b)

Figure 23.41 Coral bleaching. (a) Two colonies of the brain coral *Colpophyllia natans*. The coral on the left is a healthy brown color, whereas the coral on the right is fully bleached. (b) A large colony of partially bleached mountainous star coral (*Orbicella faveolata*).

Figure 23.42 Differential stress tolerance of a coral species associated with different *Symbiodinium* phylotypes. *Pocillopora* corals symbiotically associated with *Symbiodinium* type C1b-c were much more sensitive to a thermal stress event than the same coral species associated with *Symbiodinium* type D1. The more tolerant *Symbiodinium* type D1–*Pocillopora* association suffered low mortality. The response also suggested additional genetic variation within each *Symbiodinium* type, since the two mutualisms displayed a range of sensitivity to increasing thermal stress.

Although coral reefs are clearly threatened, there is some uncertainty in projecting their future because of a lack in basic knowledge of the heat stress capacity of individual coral–symbiont mutualisms (Figure 23.42). For example, thermal tolerance is in part conferred by the species or strain of *Symbiodinium*, and following a bleaching event, the mutualism can shift to a more thermally tolerant symbiont (Figure 23.42). Molecular studies have indicated that there are over 150 different *Symbiodinium* phylotypes, each possibly representing a distinct species with different stress tolerance. When a coral is bleached, a more heat-tolerant symbiont can replace the bleached species, likely by symbiont swapping. In this process, the species shift results from the more robust growth of a more heat-tolerant variant already associated with the coral but in very low numbers; the variant then thrives following loss of the original symbiont and the bleaching event. Because the type of symbiont influences the ability of the coral to adapt to stresses associated with climate change, a more complete understanding of this adaptive response to thermal stress, and the limits of the response, is essential for predicting the future health of corals, their symbionts, and the spectacular and ecologically important reefs that they build.

In the final part of this chapter, we explore the symbionts of the mammalian gut of herbivorous animals as a prelude to our coverage of the human microbiome in Chapter 24.

Check Your Understanding

- Where do *Symbiodinium* cells localize within the coral skeleton and within individual coral cells?
- Describe two functions of the calcium carbonate skeleton of the stony corals.
- Besides thermal stress, list some environmental factors contributing to coral bleaching.

V • Mammalian Gut Systems as Microbial Habitats

The guts of herbivorous animals are modified in such a way as to support the growth of dense populations of anaerobic microorganisms that specialize in the digestion of plant fibers. Consumption of the products of fiber digestion and the microbes themselves allows the animal to live on a plant diet rich in carbohydrates but poor in protein.

The evolution of animals has been shaped in part by a long history of symbiotic associations with microorganisms and includes vertebrates as well as the invertebrate systems we just explored. We end this chapter by considering microbial symbioses with herbivorous animals. Microbes inhabit all sites on mammalian bodies, but the greatest diversity and density of microbes are found in the mammalian gut, and so we center our discussion there.

23.14 Alternative Mammalian Gut Systems

Some mammals are *herbivores*, consuming only plant materials, whereas others are *carnivores*, eating primarily the flesh of other animals. *Omnivores* eat both plants and animals. As Figure 23.43 indicates, closely related mammals have evolved adaptations for differing diets. Notice that mammals of different lineages independently evolved the herbivorous lifestyle, mostly during the Jurassic period, an era in Earth’s history of roughly 60 million years beginning about 200 million years ago.

Figure 23.43 Phylogenetic tree showing multiple origins of herbivory among mammals. Some of the herbivores listed are foregut fermenters, while others are hindgut fermenters (see Figure 23.44). Instead of animal flesh, some mammalian carnivores eat only insects (the *insectivores*, such as bats), or fish (the *piscivores*, such as the river otter).

The massive evolutionary radiation of mammals during the Jurassic led to the evolution of several feeding strategies. Most mammalian species evolved gut structures that foster mutualistic associations with microorganisms. As anatomical differences evolved, microbial fermentation remained important or essential in mammalian digestion. *Monogastric* mammals, such as humans, have a single compartment, the stomach, positioned before the intestine. Such animals may get a substantial part of their energy requirement from microbial fermentation of otherwise indigestible foods in the lower intestine, while herbivores are totally dependent on such fermentations.

Plant Substrates

Microbial associations with various herbivorous animals led to the capacity to catabolize plant fiber, the structural component of plant cell walls. Fiber is composed primarily of insoluble polysaccharides, of which cellulose is the most abundant component. Mammals—and indeed virtually all animals—lack the enzymes necessary to digest cellulose and certain other plant polysaccharides. However, many microbes have genes encoding the hydrolases and polysaccharide lyases required to decompose these polysaccharides.

As the most abundant organic compound on Earth and one composed exclusively of glucose, *cellulose* offers a rich source of carbon and energy for animals that can digest it. The two primary traits that evolved to support herbivory are (1) an enlarged anoxic fermentation chamber for holding ingested plant material and (2) an extended retention time—the time that ingested material remains in the gut. A longer retention time allows for a longer association of microorganisms with the ingested material and thus a more complete degradation of the plant polymers.

Digestion Systems of Herbivores

Two digestive patterns have evolved in herbivorous mammals, foregut and hindgut. In herbivores with a *foregut* fermentation, the microbial fermentation chamber *precedes* the small intestine. This gut architecture originated independently in ruminants—such as cattle and sheep—colobine monkeys, sloths, and macropod marsupials (Figure 23.44). These all share the common feature that ingested nutrients are degraded by the gut microbiota *before* reaching the acidic stomach and small intestine. We examine the digestive processes of ruminants, as examples of foregut fermenters, in the next section.

Foregut fermenters Examples: Ruminants (photo 1), colobine monkeys, macropod marsupials, hoatzin (photo 2)

Hindgut fermenters Examples: Cecal animals (photos 3 and 4), primates, some rodents, some reptiles

Figure 23.44 Variations on vertebrate gut architecture. All vertebrates have a small intestine but vary in other gut structures. Most host absorption of dietary nutrients occurs in the small intestine, whereas microbial fermentation can occur in the forestomach, cecum, or large intestine (colon). Foregut fermentation is found in four major clades of mammals and one avian species (the hoatzin). Hindgut fermentation, either in the cecum or large intestine/colon, is common to many clades of mammals (including humans), birds, and reptiles. Compare with Figure 23.43.

Horses and rabbits are herbivorous mammals, but they are not foregut fermenters. Instead, these animals are *hindgut* fermenters. They have only one stomach but use an organ called the *cecum*, a digestive organ located between the small and large intestines, as their fermentation vessel (Figure 23.44). The cecum contains fiber- and cellulose-digesting (cellulolytic) microorganisms. Mammals, such as the rabbit, that rely primarily on microbial breakdown of plant fiber in the cecum are called *cecal fermenters*. In other hindgut fermenters, both the cecum and colon are major sites of fiber breakdown by microorganisms.

Anatomical differences among monogastric mammals, foregut fermenters, and hindgut fermenters are summarized in Figure 23.44. Nutritionally, foregut fermenters have an advantage over hindgut fermenters in that the cellulolytic microbial community of the foregut eventually passes through an acidic stomach. As this occurs, most microbial cells are killed by the acidity and become a protein source for the animal. By contrast, in animals such as horses and rabbits, the remains of the cellulolytic community pass out of the animal in the feces because of its position posterior to the acidic stomach. For this reason, many hindgut fermenters, for example, rabbits, commonly eat their own feces (a phenomenon called *coprophagy*) in order to recover protein from the microbial cells.

rumen

Check Your Understanding

- How do animals with foregut and hindgut fermentation differ in recovery of nutrients from plants?
- How does retention time affect microbial digestion of food in a gut compartment?

23.15 The Rumen and Rumen Activities

Earth's dominant herbivores are the *ruminants* (Figure 23.44), mammals that possess a special foregut digestive organ, the **rumen**, within which cellulose and other plant polysaccharides are digested by microorganisms. Some of the most important domesticated animals—cows, sheep, and goats—are ruminants. Camels, buffalo,

deer, reindeer, caribou, and elk are also ruminants. Because the human food economy depends to a great extent on ruminant animals, rumen microbiology is of considerable economic significance and importance.

Rumen Anatomy

Unique features of the rumen as a site of cellulose digestion are its relatively large size (capable of holding 100–150 liters in a cow, 6 liters in a sheep) and its position in the gastrointestinal system *before* the acidic stomach. The rumen's warm and constant temperature (39°C), narrow pH range (5.5–7, depending on when the animal was last fed), and anoxic environment are also important factors in overall rumen function. **Figure 23.45a** shows the relationship of the rumen to other parts of the ruminant digestive system. The digestive processes and microbiology of the rumen have been well studied, in part because it is possible to remove samples for analysis by way of a sampling port, called a *fistula*, implanted into the rumen of a cow (Figure 23.45b) or a sheep.

After a cow swallows its food, the food enters the first chamber of the four-compartment stomach, the reticulum. Partially digested plant materials flow freely between the rumen and reticulum, sometimes referred to together as the *reticulo-rumen*. The main function of the reticulum is to collect smaller food particles and move them to the omasum. Larger food particles (called *cud*) are regurgitated, chewed, mixed with saliva containing bicarbonate, and returned to the reticulo-rumen where they are digested by rumen bacteria. Solids may remain in the rumen for more than a day during digestion. Eventually, small and more thoroughly digested food particles are passed to the omasum and from there to the abomasum, an organ similar to a true, acidic stomach. In the abomasum, chemical digestive processes begin that continue in the small and large intestine.

Microbial Fermentation in the Rumen

Food remains in the rumen for 20–50 h depending on the feeding schedule and other factors. During this relatively long retention

(a)

(b)

Figure 23.45 The rumen. (a) Schematic diagram of the rumen and gastrointestinal system of a cow. Food travels from the esophagus into the reticulo-rumen, consisting of the reticulum and rumen. The reticulum collects smaller digesta particles and moves them into the omasum. Larger particles remain in the rumen and are regurgitated as cud (partially digested fiber). Cud is chewed until food particles are small enough to pass from the reticulum into the omasum, abomasum, and intestines, in that order. The abomasum is an acidic vessel, analogous to the stomach of monogastric animals like pigs and humans. (b) Photo of a fistulated Holstein cow. The fistula, shown unplugged, is a sampling port that allows access to the rumen.

Shirley D. Beek, Dept. Animal Science, Southern Illinois Univ.

Figure 23.46 Metabolic sequences and biochemical reactions in the rumen. The major pathways are solid lines; dashed lines indicate minor pathways. Approximate steady-state rumen levels of volatile fatty acids (VFAs) are acetate, 60 mM; propionate, 20 mM; butyrate, 10 mM.

time, cellulolytic microorganisms hydrolyze cellulose, which frees glucose. The glucose then undergoes bacterial fermentation with the production of **volatile fatty acids (VFAs)**, primarily *acetic*, *propionic*, and *butyric* acids, and the gases carbon dioxide (CO₂) and methane (CH₄) (Figure 23.46). The VFAs pass through the rumen wall into the bloodstream and are oxidized by the animal as its main source of energy. The gaseous fermentation products CO₂ and CH₄ are released by eructation (belching).

The rumen contains enormous numbers of bacteria (10¹⁰–10¹¹ cells/g of rumen contents). Most of the bacteria adhere tightly to food particles. These particles proceed through the gastrointestinal tract of the animal where they undergo further digestive processes similar to those of nonruminant animals. Bacterial cells that digested plant fiber in the rumen are themselves digested in the acidic abomasum. Because bacteria living in the rumen biosynthesize amino acids and vitamins, the digested bacterial cells are a major source of protein and vitamins for the animal.

Check Your Understanding

- What physical and chemical conditions prevail in the rumen?
- What are VFAs, and of what value are they to the ruminant?

23.16 Rumen Microbes and Their Dynamic Relationships

Enormous numbers of prokaryotic and eukaryotic cells are present in the rumen, even greater than those present in fertile soils (◀ Section 20.7). These include *Bacteria* and *Archaea* as well as various fungi and nonphototrophic protists. Together these microbes constitute a highly integrated and efficient microbial community whose dynamics vary according to the types and amounts of fermentable material consumed.

Rumen *Bacteria* and *Archaea*

Anaerobic *Bacteria* and *Archaea* dominate in the rumen because it is a strictly anoxic compartment, and some anaerobic microbial eukaryotes are also present. Cellulose is converted to fatty acids, CO₂, and CH₄ (Figure 23.46) in a multistep microbial food chain, with several different anaerobes participating in the process. Analysis of 16S rRNA gene sequences from rumen samples indicate that the typical rumen contains 300–400 bacterial species (◀ Section 13.12; Figure 23.47), more than ten times higher than culture-dependent diversity estimates. Molecular surveys also show that species of *Firmicutes* and *Bacteroidetes* dominate bacterial diversity in the rumen, while methanogens make up virtually the entire archaeal population (Figure 23.47).

Several rumen anaerobes have been cultured and their physiology characterized (Table 23.5). Various rumen bacteria hydrolyze cellulose to sugars and ferment the sugars to VFAs. *Fibrobacter succinogenes* and *Ruminococcus albus* are the two most abundant cellulolytic rumen anaerobes. Although both organisms produce cellulases, *Fibrobacter*, a gram-negative bacterium, produces enzymes localized to its outer membrane, whereas *Ruminococcus*, a gram-positive bacterium (and therefore lacking an outer membrane), produces a cellulose-degrading protein complex bound to its cell wall. However, in both cases, cells of *Fibrobacter* and *Ruminococcus* need to physically bind to cellulose particles in order to degrade them. The gram-positive bacterium *Butyrivibrio* also participates in the digestion of plant cell wall polymers, specializing in the digestion of hemicellulose components such as xylan.

Rumen Protists and Fungi

In addition to huge populations of *Bacteria* and *Archaea*, the rumen has characteristic populations of ciliated protists (Chapter 18) present at a density of about 10⁶ cells/ml. Many of these protists are obligate anaerobes, a physiology that is rare among eukaryotes. Although these protists are not essential for rumen fermentation, they contribute to the overall process. In fact, some protists are able to hydrolyze cellulose and starch and ferment glucose with the production of the same VFAs formed by cellulose-fermenting bacteria (Figure 23.46 and Table 23.5). Rumen protists also consume rumen bacteria and smaller rumen protists and are likely to play a role in controlling bacterial densities in the rumen. An interesting commensal interaction has been observed between rumen protists that produce VFAs and H₂ as products and methanogenic bacteria that consume the H₂, producing CH₄. Because their cells autofluoresce (◀ Section 14.15 and Figure 14.37), methanogens are easily observed in rumen fluid bound to the surface of H₂-producing protists. A similar situation exists in the hindgut of termites, but in

Figure 23.47 Ruminal microbial community inferred from 16S rRNA gene sequences. Pooled analyses of 14,817 sequences from several studies of ruminant animals, including cow, sheep, goat, and deer. The data reflect prokaryotic diversity and not necessarily relative abundance. Data assembled and analyzed by Nicolas Pinel.

this case, methanogens actually live *inside* anaerobic cellulolytic protozoa (◀ Figure 21.8c, d).

Anaerobic fungi also inhabit the rumen and play a role in its digestive processes. Rumen fungi are typically species that alternate between a flagellated and a thallus form, and studies with pure cultures have shown that they can ferment cellulose to VFAs. *Neocallimastix*, for example, is an obligately anaerobic fungus that ferments glucose to formate, acetate, lactate, ethanol, CO₂, and H₂. Although a eukaryote, this fungus lacks mitochondria and cytochromes and thus lives an obligately fermentative existence. However, *Neocallimastix* cells contain a redox organelle called the *hydrogenosome*; this mitochondrial analog evolves H₂ and has otherwise been found only in certain anaerobic protists (◀ Section 18.3).

Rumen fungi play an important role in the degradation of polysaccharides other than cellulose, including a partial solubilization of lignin (the strengthening agent in the cell walls of woody plants), hemicellulose (a derivative of cellulose that contains pentoses and other sugars), and pectin.

Dynamics of the Rumen Microbial Community

If a ruminant is gradually switched from cellulose to a diet high in starch (grain, for instance), the starch-digesting *Gammaproteobacteria* *Ruminobacter amylophilus* and *Succinomonas amylolytica* grow to high numbers in the rumen. On a low-starch diet these organisms are typically minor constituents. If an animal is fed legume hay, which is high in pectin, a complex polysaccharide containing both hexose and pentose sugars, then the pectin-digesting gram-positive bacterium *Lachnospira multipara* (Table 23.5) becomes an abundant member of the rumen microbial community. Some of the fermentation products of these rumen bacteria are used as energy sources by secondary fermenters in the rumen. For example, succinate is

fermented to propionate plus CO₂ (Figure 23.46) by the bacterium *Schwartzia*, and lactate is fermented to acetate and other fatty acids by the gram-positive bacteria *Selenomonas* and *Megasphaera* (Table 23.5). Hydrogen (H₂) produced in the rumen by fermentative processes never accumulates because it is quickly consumed by methanogens for the reduction of CO₂ to CH₄. This H₂ removal facilitates greater fermentative activity because H₂ accumulation negatively affects the energetics of fermentative reactions that produce H₂ (◀ Section 14.22). Although acetate, a methanogenic substrate, is produced in large amounts in the rumen, it is absorbed by the ruminant (Figure 23.46) and thus unavailable for conversion to methane.

Dangerous and Protective Changes in the Rumen Microbial Community

Significant changes in the microbial composition of the rumen can cause illness or even death of the animal. For example, if a cow is changed abruptly from forage to a grain diet, the gram-positive bacterium *Streptococcus bovis* grows rapidly in the rumen. The normal level of *S. bovis*, about 10⁷ cells/g, is an insignificant fraction of total rumen bacterial numbers. But if large amounts of grain are fed abruptly, numbers of *S. bovis* can quickly rise to over 10¹⁰ cells/g and dominate the rumen microbial community. This occurs because grasses contain mainly cellulose, which does not support growth of *S. bovis*, while grain contains high levels of starch, on which *S. bovis* grows rapidly.

Because *S. bovis* is a lactic acid bacterium (◀ Sections 14.18 and 16.6), large populations are capable of producing large amounts of its fermentation product, lactic acid. Lactic acid is a much stronger acid than the VFAs produced during normal rumen function (Figure 23.46). Lactate production thus acidifies the rumen below its lower functional limit of about pH 5.5, thereby disrupting the activities of normal rumen bacteria. Rumen acidification, a condition called *acidosis*, causes inflammation of the rumen epithelium, and severe acidosis can cause hemorrhaging in the rumen, acidification of the blood, and death of the animal. Despite this dangerous condition typically associated with abrupt feeding changes, ruminants such as cattle can be fed a diet exclusively of grain. However, to avoid acidosis, the animals must be switched from forage to grain *gradually* over a period of many days. The slow introduction of starch selects for VFA-producing starch-degrading bacteria (Table 23.5) instead of *S. bovis*. Under these conditions, normal rumen functions continue, and the animal remains healthy.

The overgrowth of *S. bovis* is a potent example of how a single microbial species can have a deleterious effect on animal health. In

TABLE 23.5 Characteristics of some rumen Bacteria and Archaea

^aExcept for the methanogens, which are *Archaea*, all organisms listed are *Bacteria*.
^bThese species also degrade xylan, a major plant cell wall polysaccharide.
^cAlso degrades starch.
^dAlso ferments amino acids, producing NH₃. Several other rumen bacteria ferment amino acids as well, including *Peptostreptococcus anaerobius* and *Clostridium sticklandii*.

contrast, there is at least one well-studied example of how a single bacterial species can *enhance* the health of ruminant animals. This occurs in animals fed the tropical legume *Leucaena leucocephala*. This plant has very high nutritional value but contains an amino acid–like compound called *mimosine* that is converted to the toxic compounds

Figure 23.48 Conversion of mimosine to toxic pyridine and pyridone metabolites by ruminal microorganisms. Mimosine is converted to toxic 3,4-DHP by normal ruminal microbiota. *Synergistes jonesii* converts 3,4-DHP to nontoxic metabolites through a 2,3-DHP intermediate, preventing buildup of toxic metabolites of mimosine.

3-hydroxy-4(1H)-pyridone (3,4-DHP) and 2,3-dihydroxypyridine (2,3-DHP) by rumen microorganisms (Figure 23.48). The observation that ruminants in Hawaii, but not Australia, could feed on *Leucaena* without toxic effect led investigators to hypothesize that further metabolism of DHP by bacteria present in Hawaiian ruminants alleviated DHP toxicity. This was subsequently confirmed by the isolation of the bacterium *Synergistes jonesii*, an anaerobe related to *Deferribacter* (◀ Section 16.22) but not closely related to any other rumen bacteria. Inoculation of Australian ruminants with cells of *S. jonesii* conferred resistance to mimosine by-products, allowing the animals to feed on *Leucaena* without ill effect.

The success of this single-organism modification of the rumen microbial community has encouraged further studies of this sort, including genetic engineering of bacteria to improve their ability to utilize available nutrients or to detoxify toxic substances. A notable success has been inoculation of the rumen of sheep with genetically engineered cells of *Butyrivibrio fibrisolvens* (Table 23.5) containing a gene encoding the enzyme fluoroacetate dehalogenase. This successfully prevented fluoroacetate poisoning of sheep fed plants containing high levels of this highly toxic citric acid cycle inhibitor.

With this extensive background on the symbiotic microbial communities associated with various nonhuman animals, we now move on to Chapter 24 where the microbial world that populates and affects the health of human beings will be center stage and considered in some detail.

Check Your Understanding

- What groups of *Archaea* are present in the rumen, and how do they contribute to ruminant nutrition?
- Fungi and protists are eukaryotic microbes. How can they survive in the anoxic rumen?
- Give an example of how changes in the type of fiber given to a ruminant can result in a transition in its rumen microbes.
- Why is the metabolism of *Streptococcus bovis* of special concern for ruminant nutrition, and under what conditions is this bacterium a threat to the animal's health?

CHAPTER REVIEW

I • Symbioses Between Microorganisms

- 23.1** Lichens are a mutualistic association between one or two species of fungi and an oxygenic phototroph, either an alga or a cyanobacterium.

Q How does a phototroph benefit from associating with a fungus in lichen symbiosis?

- 23.2** The consortium "*Chlorochromatium aggregatum*" is a mutualism between a phototrophic green sulfur bacterium and a motile heterotrophic bacterium. Mutual benefit is based on the phototroph supplying organic matter to the heterotroph in exchange for motility that permits rapid repositioning in stratified lakes to obtain optimal light and nutrients.

Q Considering its metabolic properties, what advantage to the phototroph in the "*Chlorochromatium aggregatum*" consortium might rapid repositioning confer?

- 23.3** Anaerobic microorganisms capable of direct interspecies electron transfer use cytochrome-rich surface structures to form direct electrical connections between cells of different species, such as between a methane-oxidizing archaeon and a sulfate-reducing bacterium. Electrons originating from the oxidation of a hydrocarbon compound (such as methane or ethane) by one species are directly transferred to the electrically connected second organism, which then uses those electrons to reduce an electron acceptor such as sulfate.

Q Assuming that methane was the only available energy source for a sulfate-reducer-ANME consortium, why can it be said that neither partner could exist without the other?

II • Plants as Microbial Habitats

- 23.4** One of the most agriculturally important plant-microbial symbioses is that between legumes and nitrogen-fixing bacteria. The bacteria induce the formation of root nodules within which nitrogen fixation occurs. The plant provides the energy needed by the root nodule bacteria, and the bacteria provide fixed nitrogen for the plant.

Q Describe the steps in the development of root nodules on a leguminous plant. What is the nature of the recognition between plant and bacterium, and how do Nod factors help control this? How does this compare with recognition in the *Agrobacterium*-plant system (Section 23.6)?

- 23.5** Mycorrhizae are mutualistic associations between fungi and the roots of plants that allow the plant to extend its root system via intimate interaction with an extensive network of fungal mycelia. Both ectomycorrhizae and endomycorrhizae are known. The mycelial network provides the plant with essential inorganic nutrients, and the plant, in turn, supplies organic compounds to the fungus.

Q How do mycorrhizae improve the growth of trees? In what way(s) are the root nodule and mycorrhizal symbioses similar? In what major way do they differ?

- 23.6** The crown gall bacterium *Agrobacterium* enters into a unique relationship with plants. Part of the Ti plasmid in the bacterium can be transferred into the genome of the plant, initiating crown gall disease. The Ti plasmid has also been used for the genetic engineering of crop plants.

Q Compare and contrast the production of a plant tumor by *Agrobacterium tumefaciens* and a root nodule by a *Rhizobium* species. In what ways are these structures similar? In what ways are they different? Of what importance are plasmids to the development of both structures?

III • Insects as Microbial Habitats

- 23.7** A large proportion of insects have established obligate mutualisms with bacteria, the basis of the mutualism often being bacterial biosynthesis of nutrients such as amino acids that are absent from the food the insect feeds on. Long-established obligate mutualisms are marked by extreme genome reduction of the symbiont, with retention of only those genes essential for the mutualism.

Q How is it possible for aphids to feed only on the carbohydrate-rich but otherwise nutrient-poor sap of phloem vessels in plants? Why do symbionts that are transmitted horizontally show less genome reduction, as opposed to the significant genome reduction observed in heritable symbionts?

- 23.8** The symbionts of many insects produce defensive chemicals that are toxic to specific pathogens and predators of the insect. The biosynthetic capacity to make defensive chemicals often resides on mobile genetic elements such as plasmids and transposons, allowing insects and their protective symbionts to adapt to changing predator threats by horizontal gene transfer.

Q How would horizontal versus vertical transmission of symbionts influence transfer of genes for defensive chemicals between different strains or species of symbionts?

- 23.9** Termites associate symbiotically with bacteria and protists capable of digesting plant cell walls. The unique termite gut configuration and the hindgut microbial community composed largely of cellulolytic bacteria and protists and acetogenic bacteria result in high levels of acetate, the primary source of carbon and energy for the termite.

Q How do the microbial communities of higher and lower termite guts differ in composition and degradation of cellulose?

IV • Other Invertebrates as Microbial Habitats

23.10 Several genera of primarily marine microorganisms have the capacity to generate light through a biochemical process known as bioluminescence, sometimes forming symbiotic associations with marine animals. A light-emitting organ on the underside of the Hawaiian bobtail squid provides a habitat for bioluminescent cells of the bacterium *Aliivibrio fischeri*. From the mutualism in the light organ, the squid gains protection from predators while the bacterium benefits from a habitat in which it grows quickly and contributes cells to its free-living population.

Q How is the correct bacterial symbiont selected in the squid–*Aliivibrio* symbiosis?

23.11 Most invertebrates living on the seafloor near regions receiving hydrothermal fluids have established obligate mutualisms with chemolithotrophic bacteria. These mutualisms are nutritional, allowing the invertebrates to thrive in an environment enriched in reduced inorganic materials, such as H_2S , that are abundant in vent fluids. The invertebrates provide the symbionts an ideal nutritional environment in exchange for organic nutrients.

Q Why is the genome of the tube-worm symbiont thought to be so much larger than the genomes of insect symbionts?

23.12 Entomopathogenic nematodes have established symbiotic associations with species of *Photorhabdus* and *Xenorhabdus* bacteria. Following invasion of an insect by the nematode, bacterial symbionts are released into the insect's hemolymph and multiply rapidly by thwarting the insect's immune system, killing the insect by the release of toxins and digestive enzymes. When nutrients are depleted, the nematodes then transition to a nonfeeding juvenile form that harbors the symbiont in a specialized receptacle and goes on to infect another insect.

Q Why are entomopathogenic nematodes so attractive for the biocontrol of insect pest species?

23.13 The mutualism between the dinoflagellate *Symbiodinium* and the stony corals produces the extensive worldwide coral reef ecosystems that sustain a tremendous diversity of marine life. Coral bleaching caused by climate change threatens these ecosystems.

Q How have both partners in the cnidarian–dinoflagellate mutualism evolved adaptations for nutritional exchange?

V • Mammalian Gut Systems as Microbial Habitats

23.14 Microbial fermentation is important for digestion in all mammals. Several microbial mutualisms have evolved in different mammals that allow for the digestion of different types of food. Herbivores derive almost all of their carbon and energy from plant fiber.

Q From a gastrointestinal standpoint, how do a sheep and a rabbit differ and how are they similar?

23.15 The rumen, the foregut digestive organ of ruminant animals, specializes in cellulose digestion, which is carried out by various microbes. The position of the rumen at the beginning of the animal's digestive tract allows for protein recovery when rumen microbes are killed in the animal's acidic stomach.

Q How can the rumen be studied and sampled in a living animal?

23.16 *Bacteria*, protists, and fungi in the rumen produce volatile fatty acids that provide energy for the ruminant while *Archaea* convert CO_2 and H_2 into CH_4 that is released to the atmosphere. Rumen microorganisms synthesize vitamins and amino acids and are also a major source of protein—all used by the ruminant.

Q Give an example of two rumen microbes and describe how they contribute to herbivore nutrition.

APPLICATION QUESTIONS

1. Choose one invertebrate discussed in this chapter and compare its microbial symbionts with those in the rumen. Why is the microbial community of these two animals considerably different? In your comparison, consider major aspects of the biology of the host (body temperature, organ systems need to resist predators, and the like), its habitat, and its food source(s), as well as the biology of the symbionts, including their habitat, metabolism, and genome characteristics.
2. Imagine that you have discovered a new animal that consumes only grass in its diet. You suspect it to be a ruminant and have available a specimen for anatomical inspection. If this animal

is a ruminant, describe the position and basic components of the digestive tract you would expect to find and any key microorganisms and substances you might look for. What metabolic types of microorganisms or specific genes would you predict would be present?

3. Why would you be very surprised to find the exact same microbial symbionts inhabiting a lichen and the rumen of a cow? Consider both the physical and chemical conditions of the habitat and the requirement for specific microbes to be present in order for the symbiosis to be successful.

CHAPTER GLOSSARY

Arbuscule a branched or coiled hyphal structure within cells of the inner cortex of plants with a mycorrhizal infection

Autoinduction the induction of transcription of a set of genes, such as those responsible for bioluminescence, that occurs only when population density is great enough

Bacteriocyte a specialized insect cell in which bacterial symbionts reside

Bacteriome a specialized region in several insect groups that contains insect bacteriocyte cells packed with bacterial symbionts

Bacteroid a misshapen rhizobial cell inside a leguminous plant root nodule; can fix N_2

Bioluminescence the enzymatic production of visible light by living organisms

Coevolution evolution that proceeds jointly in a pair of intimately associated species owing to the effects each has on the other

Commensalism a symbiosis in which one symbiotic partner benefits and the other is unaffected

Consortium a two- or more-membered association of bacteria, usually living in an intimate symbiotic fashion

Infection thread in the formation of root nodules, a cellulosic tube through which *Rhizobium* cells can travel to reach and infect root cells

Leghemoglobin an O_2 -binding protein found in root nodules

Lichen one or two species of fungi and an alga (or cyanobacterium) living in symbiotic association

Mutualism a symbiosis in which both partners benefit

Myc factors lipochitin oligosaccharides produced by mycorrhizal fungi to initiate symbiosis with a plant

Mycorrhizae a symbiotic association between a fungus and the roots of a plant in which nutrients are transferred in both directions

Nod factors lipochitin oligosaccharides produced by root nodule bacteria that help initiate the plant–bacterial symbiosis

Parasitism a symbiosis in which one symbiotic partner benefits and the other is harmed

Root nodule a tumorlike growth on plant roots that contains symbiotic nitrogen-fixing bacteria

Rumen the major fermentation vessel in the multichambered gut of ruminant animals, where most cellulose digestion occurs

Symbiosis an intimate relationship between organisms, often developed through prolonged association and coevolution

Ti plasmid a conjugative plasmid in the bacterium *Agrobacterium tumefaciens* that can transfer genes into plants

Volatile fatty acids (VFAs) also called short-chain fatty acids (SCFAs), these are the major fatty acids (acetate, propionate, and butyrate) produced during fermentation in the rumen

Microbial Symbioses with Humans

24

MICROBIOLOGYNOW

One of the Most Abundant Viruses on Earth Discovered First in the Human Viral Microbiome

Past discoveries of novel viruses have required that the host they naturally infect first be identified and isolated. However, since most bacterial and archaeal diversity is still uncultured, new viral discoveries were few until next-generation sequencing allowed virus-like particles collected from the environment to be characterized directly. Today, viral metagenomics is the primary method of viral discovery and has revealed a vast reservoir of novel genetic diversity, most of which has no precedent in known viruses.

One of the most remarkable findings from metagenomic viral studies thus far has been the discovery of a human gut-associated bacterial virus (bacteriophage) that comprises up to 90% of viral genomic sequences found there. The virus was named *crAssphage* for the *cross-assembly* method used to reconstruct its roughly 100-kbp circular DNA genome from metagenomic sequences obtained from different subjects. Genomic sequences from *crAssphage* were found to match more than one-fifth of all viral genomic sequences recovered from marine, terrestrial, and animal sources. Thus, *crAssphage*-like viruses are probably one of the most abundant biological

entities on Earth! But a remaining mystery was “Whom do *crAssphage*-like viruses infect?”

The hunt was on using the standard method of screening cultured bacteria for infection by *crAssphage*. By screening 54 gut species for infection by phage-enriched fecal filtrates, the first *crAssphage* virus was isolated on the gut bacterium *Bacteroides intestinalis*; the phage has an icosahedral capsid about 80 nm in diameter (photo) and a short tail (arrows). The *crAssphage*-like viruses are now known to comprise a large viral family predicted to infect many species of *Bacteroidetes* in diverse environments.

Since changes in the gut virome are associated with human gastrointestinal abnormalities such as inflammatory bowel disease and malnutrition, we can expect that the isolation of new bacteriophages discovered through metagenomics will reap important rewards for human health.

I • Structure and Function of the Healthy Adult Gastrointestinal and Oral Microbiomes

Our bodies host tremendous numbers of microorganisms distributed among different body sites, together comprising the human microbiome. Colonization begins at birth, and the assembly, composition, and activities of our gastrointestinal and oral microbiomes in particular greatly influence our health and predisposition to disease.

The human body contains huge numbers of microbes—our **microbiome**—that our very existence depends on. We begin our consideration of this microbial menagerie with an overview of the human microbiome and then consider the **microbiota**—the types of organisms present in specific regions of the body.

The clinical benefits of knowing a person's microbiome seem promising and include the development of biomarkers for predicting predisposition to specific diseases, the design of therapies increasing or decreasing the activities of selected microbial species in particular body sites, personalized drug therapies, and tailor-made probiotics (Section 24.12). However, there is a caveat. Not only is a person affected by his or her microbiota, but a person's microbiota also responds to his or her activities, health, and diet. Thus, cause and effect relationships are often not immediately obvious and can sometimes be difficult to sort out.

Microbiome studies to date have revealed an incredible diversity of microbial life in and on the human body and have signaled several likely connections between the microbial composition of a body site and the health status of the person. However, at this point most microbial associations with health or disease states are only correlations or are based on animal models; a firm causal relationship between a person's microbiome and health status has been well established in only a few instances.

24.1 Overview of the Human Microbiome

The sites of the human body inhabited by microorganisms include the mouth, nasal cavities, throat, stomach, intestines, urogenital tracts, and skin (Figure 24.1). It is estimated that the microbes in the **human microbiome** number around 10^{13} cells, which is about the same as the number of human cells in a single person. Together, the human body as the **host** and its associated microbes constitute a *host–microbiome supraorganism*. For example, the gut microbial community in the healthy human was once considered to consist of merely commensal microbes, but we now know that gut microbes are critical to development of the immune system, overall health later in life, and predisposition to disease. This recognition has stimulated the formation of several national and international research programs devoted to examining the human microbiome in great detail (Table 24.1). Collectively, these studies have shown that on the one hand the microbial diversity between individuals is so great that no one microbial species is present in all individuals, but on the other hand, particular microbial groups typically dominate.

Figure 24.1 Microbial habitats of the human body. Primary body sites characterized in ongoing studies of the human microbiome (see Table 24.1).

Methodologies for Probing the Human Microbiome

Because the vast majority of microorganisms cannot yet be readily cultured or enumerated using growth-dependent approaches, it was the development of advanced nucleic acid sequencing methods (Chapters 10 and 19) that first offered the means to initiate a robust census of microbial diversity and abundance patterns in humans. The current “megasequencing era” has allowed microbiologists to quickly compare the microbiomes of different individuals and to begin to resolve the dynamic relationship between the microbiome and host history, genetics, health status, and diet.

This focus on molecular sequences in microbiome studies does not diminish the importance of cultivation in the study of the human microbiome. Indeed, since sequence-based surveys have shown that many human-associated microorganisms have not yet been isolated, there has been a renaissance in efforts to bring those microorganisms

TABLE 24.1 Major human microbiome research programs

Research program	Participating countries	Programmatic objectives
MetaGenoPolis	France	Demonstrate the impact of the human gut microbiota on health and disease using metagenomics technology
International Human Microbiome Standards	European Commission	Optimize methods for the assessment of the effects of the gut microbiome on human health through the standardization of procedures and protocols
Korean Twin Cohort Project	Korea	Characterize microbiota associated with epithelial tissue in a twin cohort study group, with the goal of identifying targets for early disease diagnosis and prevention
NIH Human Microbiome Project (HMP)	USA	Characterize the microbes that live in and on the human body, and assess the ability to demonstrate correlations of changes of the human microbiome with health
Canadian Human Microbiome Initiative	Canada	Characterize the microorganisms colonizing the human body. Evaluate their relationship to health and examine compositional changes associated with chronic disease
NIH Jumpstart Program	USA	Generate the complete genome sequences of 200 bacterial strains isolated from the human body; recruit donors for securing samples from five body regions, and perform 16S rRNA and metagenomic sequence analysis of the sampled body regions
American Gut: An Open Platform for Citizen Science Microbiome Research	USA	Crowdsourcing model to secure fecal samples for comparative 16S rRNA, metagenomic, and metabolomic analyses

into culture, and the development of successful culture conditions has been guided by the results of metagenomic sequencing and the other omics tools of the microbial ecologist (◀ Section 19.8). Using the omics toolbox, longitudinal studies of “at risk” human study groups have explored how the composition of the human microbiome, often determined early in life, affects such major diseases as obesity, diabetes, and inflammatory bowel disease. The results clearly show microbial links to these conditions.

A Snapshot of the Human Microbiome

An overview of the bacterial composition of the four heavily colonized human body sites (skin, oral, urogenital, and gastrointestinal), as defined by higher taxonomic levels, is shown in Figure 24.2. In each site, one group of bacteria tends to dominate, and at each site, the dominant group is different. For example, the diversity of gram-positive bacteria is greatest on the surface of the skin and the urogenital tract while the diversity of gram-negative bacteria is greatest in the gastrointestinal tract. The following sections in this chapter will examine each of these sites at a higher resolution to more fully describe the diversity of microbes inhabiting the human body. Later sections will address the functional significance of the microbiome and how it might be modified for health benefit.

A remarkable feature that emerged early in human microbiome studies is the individuality and resilience of the different microbial communities. For example, an adultlike gut microbiome develops in an individual within three years of birth and shows a species composition unique to that individual that is retained throughout life. An individual’s microbiome also has tremendous plasticity, responding quickly to disturbances such as changes in diet, antibiotic therapy, or cohabitation with people and pets. However, following the removal of the disturbance, an individual’s unique microbiome tends to reemerge.

As we will explore in later sections, differences in the strains or even species of microbes in people’s microbiomes likely influence their response to therapies, such as fecal transplants designed to alter their microbiota for health benefit (Section 24.11). Similarities in the microbiomes of different individuals are more evident at higher bacterial taxonomic levels (such as phyla, families, and to some extent genera) rather than at the species and strain levels.

We start our tour of the human microbiome with a focus on the microbial communities that inhabit the gut, the human body site most heavily colonized by microbes and a site where the absence or presence of specific microbes may play a major role in an individual’s overall health or lack thereof.

Check Your Understanding

- Which major body sites do microbes most heavily colonize?
- What methods have been used to assess the human microbiome?
- Why might knowing our microbiome and how it functions be useful?

24.2 Gastrointestinal Microbiota

The human gastrointestinal tract consists of the stomach, small intestine, and large intestine (Figure 24.3), and is responsible for the digestion of food and the absorption of nutrients; many important nutrients are also produced by the indigenous microbiota. Starting with the stomach, the human digestive tract is a long, folded tube of nutrients mixed with microbes, primarily species of *Bacteria*. The host and its gut microorganisms share the easily digestible nutrients. The nutrients are moved through this tube, encountering ever-changing microbial communities and abundance (Figure 24.3).

Figure 24.2 Overview of major microbial populations in the body sites sampled by human microbiome projects. Diversity among body sites was evaluated by 16S rRNA gene sequence analysis (◀ Section 13.11). Note that each body site tends to be dominated by one population type: skin by *Propionibacterium* species; oral by *Streptococcus* species; urogenital by *Lactobacillus* species; and gastrointestinal by *Bacteroides* species.

The human gastrointestinal tract has about 400 m² of surface area and is home to a total of about 10¹³ microbial cells. In the human duodenum, ingested food passed down from the stomach is blended with bile, bicarbonate, and digestive enzymes. About 1–4 h after ingestion, food reaches the gut (the large intestine, with near-neutral pH) and total bacterial numbers have increased from about 10⁴/g (in the stomach) to 10⁸/g (in the small intestine) to 10¹¹–10¹² per g (in the large intestine) (Figure 24.3).

The Stomach and Small Intestine

The stomach was long thought to be either sterile or only minimally populated until the discovery in 1983 that the highly acid-tolerant bacterium *Helicobacter pylori* colonizes the stomachs of about 50% of all humans. This discovery prompted a closer inspection of the microbiology of the human stomach through both cultivation and 16S rRNA sequence analyses. The stomach is now recognized as the home of a vibrant bacterial community with hundreds of phylotypes distributed between the gastric lumen (pH 1–2) and the mucus layer of the wall (pH 6–7). Although low pH prevents bacterial overgrowth, the healthy human stomach holds a core microbiome that is distinct from the transient passage of ingested oral populations and is dominated by *Bacteroidetes* (*Prevotella*), *Firmicutes* (*Streptococcus*, *Veillonella*, *Lactobacillus*), *Actinobacteria* (*Rothia*, *Propionibacterium*), *Fusobacteria*, and *Proteobacteria* (*Haemophilus*, *Methylobacterium*).

Firmicutes, *Bacteroidetes*, and *Actinobacteria* dominate gastric fluid samples, whereas *Firmicutes* and *Proteobacteria* are more abundant in

gastric mucosal samples. When present, *H. pylori* accounts for the vast majority of stomach microbial biomass and can cause upper gastrointestinal tract disease (▶ Section 31.10). Distal to the stomach, the intestinal tract consists of the small and large intestines, each of which is divided into different anatomical segments and supports a characteristic microbiota (Figure 24.3). The small intestine has three distinct chambers, the *duodenum* and the *ileum* connected by the *jejunum*. The duodenum, adjacent to the stomach, is fairly acidic and its microbiota typically resembles that of the stomach. From the duodenum to the ileum, the pH gradually becomes less acidic and bacterial numbers increase. In the lower ileum, cell numbers of 10⁵–10⁷/gram of intestinal contents are common, even though the environment becomes progressively more anoxic. Fusiform (spindle-shaped) anaerobic bacteria are typically present, with one end attached to the intestinal wall (Figure 24.4). Whereas the colonic microbiota (next subsection) is largely supported by the degradation of complex indigestible carbohydrates, microbial residents of the small intestine must compete with the host for the rapid uptake of small carbohydrates and therefore consist of bacteria well-adapted to “feast or famine” conditions.

Structure, Cell Numbers, and Retention Times in the Large Intestine

The ileum empties into the *cecum*, the beginning of the large intestine. The *colon* makes up the rest of the large intestine. In the colon, *Bacteria* are present in enormous numbers and *Archaea* (primarily

Figure 24.3 The human gastrointestinal tract and major members of its microbiota. These taxa are representative of microorganisms found in healthy adults. Not every individual harbors all of these microorganisms.

methanogens) can be present, too, depending on the individual. The colon is essentially a fermentation vessel, with the microbiota using nutrients derived from the digestion of food (Figure 24.3). Facultative aerobes such as *Escherichia coli* are present but in much smaller numbers than other bacteria; instead, obligate anaerobes predominate. The facultative aerobes consume traces of oxygen that make it to the colon, rendering the large intestine strictly anoxic. Anoxia promotes growth of obligate anaerobes such as *Clostridium* and *Bacteroides* species; indeed, *Bacteroidetes* and gram-positive *Bacteria* account for more than 99% of all prokaryotic cells.

The total number of obligate anaerobes in the colon is enormous. *Bacteria* are by far the dominant population—bacterial cell counts of 10^{10} to 10^{11} /gram of fecal contents are typical. During the passage of food through the gastrointestinal tract, water is absorbed from the digested material, which gradually becomes more concentrated and is converted to feces (Figure 24.5). Bacteria compose about one-third of the weight of fecal matter. Organisms inhabiting the lumen of the large intestine are continuously displaced downward by the flow of material, and bacteria that are lost are continuously replaced by new growth, similar to a continuous culture system (◀ Section 4.8). The time needed for passage of material through the human gastrointestinal tract is about 24 h, and the growth rate of bacteria in the lumen averages one to two doublings per day.

A person sheds a total of about 10^{13} bacterial cells each day in feces. Most of those organisms are restricted to the lumen of the large intestine. Production of **mucin** (a thick liquid secretion containing water-soluble proteins and glycoproteins) by *goblet cells* (a specialized class of epithelial cells) in the intestinal epithelium

forms a protective layer (inner mucus layer) immediately adjacent to the intestinal epithelium (Figure 24.5). This inner mucus layer, unlike the outer mucus layer, is rarely colonized by bacteria. Goblet cells also produce various antimicrobial peptides that help prevent microbial contact with the underlying epithelium.

Figure 24.4 Microbiota in the small intestine. Scanning electron micrographs of the microbial community on epithelial cells in the mouse ileum. (a) An overview at low magnification shows long, filamentous fusiform bacteria on epithelial cells in the mouse ileum (part of the small intestine, see Figure 24.19). (b) Higher magnification shows several filaments attached at a single depression. The attachment is at the end of the filaments. Individual cells are 10–15 μm long.

Figure 24.5 Different microenvironments in the large intestine. The inner mucin layer, produced by and contacting the gut mucosa, is partly oxygenated but generally free of bacteria. The sparsely populated outer mucus layer is adjacent to the heavily colonized anoxic lumen, which receives undigested food particles from the small intestine.

Bacterial Diversity of the Large Intestine

Figure 24.6 is a molecular snapshot of bacterial diversity in the human colon as determined by 16S rRNA gene sequence analysis of feces. Two major families of *Firmicutes* (*Lachnospiraceae* and *Ruminococcaceae*) dominate gram-positive bacterial diversity in the gut and are important in the digestion of polysaccharide polymers in plant fiber, such as cellulose and pectin; these are depolymerized and the sugars fermented in the large intestine. *Ruminococcus* species play an important role in the digestion of starch and resistant starch, a form of starch common in seeds and whole grains that is not digested in the small intestine. Since fermentation of resistant starch in the colon generates beneficial short-chain fatty acids (see Section 24.9), there is increasing interest in using resistant starch as a food additive, called a *prebiotic* (see Section 24.12), to encourage the growth of ruminococci and other fermenting species.

Gut *Bacteroidetes* largely consist of different species of the genus *Bacteroides*, organisms that also specialize in the degradation of polysaccharides, although some species are proteolytic. When dietary polysaccharides are not available, or in low abundance, glycolytic *Bacteroides* use host glycans and glycoproteins derived from the mucin layer (Figure 24.5).

In contrast to the rather limited *phylum-level* gut bacterial diversity, gut *species* diversity is enormous. For instance, one study of diversity in human fecal samples (based on the analysis of millions of 16S rRNA sequences from a large sample of people) identified between 3500 and 35,000 bacterial “species,” depending on exactly how one defines a bacterial species (◀ Section 13.12). A relatively small number of these, several hundred or so, are shared by most individuals. *Archaea* (represented by a phylotype closely related to the methanogen *Methanobrevibacter smithii*), yeasts, fungi, and protists are either absent or compose only a minor part of the human gut community (compare this with the rumen, ◀ Section 23.16). When eukaryotic microbes are present, they are usually yeasts of the genus *Candida* (▶ Sections 34.1 and 34.2).

Although there is high variability from person to person in gut community composition at the species level, any particular individual’s community is relatively stable over long periods. In a longitudinal study of healthy adults, about 65% of strains persisted for at least 5 years and most strains likely remain residents for decades, perhaps even for the lifetime of an individual. Three broad gut communities (called *enterotypes*) have been described, differing primarily by the enrichment of one microbial group in each enterotype. Enterotype 1 is enriched in *Bacteroides*, enterotype 2 is enriched in *Prevotella*, and enterotype 3 is enriched in *Ruminococcus* (Figure 24.6). The enterotypes are functionally distinct, differing in capacity for producing vitamins and energy-rich metabolites that can be used by the host. Evidence also exists that a person’s enterotype influences the response to diet and drug therapy and may contribute to health or disease status in yet unknown ways.

Products of Intestinal Microbiota

Some products of gut microbial metabolism are relatively simple compounds (Table 24.2), such as the volatile fatty acids generated by microbial fermentation of plant material, as also occurs in the rumen of herbivores (◀ Figure 23.46). Other products generated by

Figure 24.6 Bacterial diversity of feces. The results are pooled analyses of approximately 1 million sequences (from 184 samples) of the V1–V3 region of the 16S rRNA gene (◀ Figure 13.24). Members of the *Bacteroidetes* and *Firmicutes* dominate the normal microbiota of the large intestine. Many of these groups are discussed in Chapters 15 and 16. Data assembled and analyzed by Nicolas Piel.

TABLE 24.2 Biochemical/metabolic contributions of intestinal microorganisms	
Process	Product or enzyme
Vitamin synthesis	Thiamine, riboflavin, pyridoxine, B ₁₂ , K
Amino acid synthesis ^a	Asparagine, glutamate, methionine, tryptophan, lysine, and others
Gas production	CO ₂ , CH ₄ , H ₂
Odor production	H ₂ S, NH ₃ , amines, indole, skatole, butyric acid
Organic acid production	Acetic, propionic, butyric acids
Glycosidase reactions	β-Glucuronidase, β-galactosidase, β-glucosidase, α-glucosidase, α-galactosidase
Steroid metabolism (bile acids)	Esterified, dehydroxylated, oxidized, or reduced steroids

^aCapacity for amino acid biosynthesis inferred from the identification of biochemical pathways encoded in gut metagenomic sequences (◀ Sections 10.7 and 19.8).

the activities of fermentative bacteria and methanogens include H₂, CO₂, and CH₄ (similar to fermentation products of the rumen) and several other substances and nutrients (Table 24.2).

Gut microbes also produce vitamins B₁₂ and K and some amino acids humans are unable to make (so-called essential amino acids, such as lysine). These essential compounds are not synthesized by humans (and vitamin B₁₂ is not present in plants) but are made by the gut microbiota and absorbed from the colon. In addition, steroids, produced in the liver and released into the intestine from the gallbladder as bile acids, are modified in the intestine by the microbiota; the modified bioactive steroid compounds are then absorbed from the gut.

Many other microbial metabolites or transformation products that can be generated in the gut have significant influence on host physiology. These include post-translationally modified peptides such as the lantibiotics and bacteriocins (Table 24.3), substances that function to help secure colonization of the producing organism by inhibiting organisms closely related to the producer. Gut bacteria can also synthesize high levels (>100 mg/day in some cases) of metabolites derived from the reduction of amino acids. These include substances such as *tryptamine*, a tryptophan metabolite thought to function as a neurotransmitter that signals the enteric nervous system, and *4-ethylphenylsulfate*, shown to affect behavior in

mice (Table 24.3). These examples suggest that an animal’s microbiome and its nervous system—called the *gut–brain axis*—are likely connected (see Explore the Microbial World, “The Gut–Brain Axis”).

The Gut Microbiome and “Educating” the Immune System

The gut microbiome has far-reaching effects on the long-term health of a human. For example, the immune system does not properly develop in the absence of microbial stimulation, and exposure to a variety of microorganisms soon after birth is essential for developing immune tolerance of beneficial microorganisms (our **normal microbiota**) and recognizing pathogens as foreign. Indeed, the result of excessive hygiene in an infant’s development may be a poorly trained immune system that is more likely to attack beneficial organisms with an inflammatory response. Such an immune status is thought to promote autoimmune conditions such as allergies, asthma, and inflammatory bowel diseases later in life.

Much of our understanding of how the immune system is trained to accept the normal microbiota comes from the study of mice (Section 24.7). For example, a key factor contributing to the successful colonization of *Bacteroides fragilis*, part of the normal microbiota of the mouse gut, is production of a “symbiosis factor” called *polysaccharide A* (Table 24.3). Polysaccharide A is a diffusible oligosaccharide derived from the *B. fragilis* outer membrane (◀ Section 2.4) that signals the host’s immune system to promote the tolerance needed for successful colonization by this bacterium. Tolerance is associated with the capacity of polysaccharide A to induce the production of cytokines (▶ Section 26.5) in the host that suppress inflammation or activate specific immune cells. *Clostridium* species also suppress inflammation and promote tolerance using a similar mechanism. Besides promoting its own colonization, *B. fragilis* has also been shown to protect mice from colitis caused by a pathogenic bacterium, *Helicobacter hepaticus*. In experimental animals colonized with *B. fragilis* mutants unable to express polysaccharide A, *H. hepaticus* colonizes the gut and elicits inflammatory bowel disease, whereas control animals colonized by wild-type *B. fragilis* do not.

The gut is a complex structure that hosts a diversity of microbes, and these examples of the “dialogue” between gut microbiota and host indicate the importance of exposing infants to a variety of microbes early in life in order to develop a healthy immune system that can readily distinguish “friend from foe.” The identification of common and variably distributed biologically active compounds

TABLE 24.3 Small bioactive molecules produced by bacteria in the large intestine			
Class	Compound	Example producer	Activity
RiPP ^a (lantibiotic)	Ruminococcin A	<i>Ruminococcus gnavus</i>	Antibiotic

^bThese small molecules promote colonization by normal microbiota.

The Gut–Brain Axis

Interactions between the gut microbiota and the host brain and general nervous system (called the *gut–brain axis*) have been gaining attention because of possible contributions to behavioral disorders. We know that there is a clear relationship between gut dysbiosis and pathologies such as inflammatory bowel disease and obesity (Section 24.9). However, gut dysbiosis is also associated with autism, a general term for a spectrum of behavioral disorders (together called *autism spectrum disorder*) that can emerge in the first 36 months of life, causing substantial impairments in social interaction and communication and marked by repetitive behaviors and unusual interests.

Human autism has been attributed to a combination of genetic and environmental factors. An environmental risk factor for a child developing autism and other behavioral disorders is maternal immune activation (MIA), which involves elevated levels of inflammatory factors in the blood, placenta, and amniotic fluid during pregnancy and can be caused, for example, by viral infection. Although the relationship between MIA during pregnancy and impaired development of the fetal central nervous system is complex, mouse models suggest that some features of autism can be alleviated by correcting associated defects in the gut microbial community.

The offspring of mice in which MIA has been induced display autism-like behaviors, such as communication defects and anxiety (Figure 1a, b). Those behavioral changes are associated with a loss of intestinal integrity, a shift in the composition of gut clostridial and bacteroidal populations reminiscent of changes observed in autistic humans, and a 46-fold increase in serum levels of the chemical *4-ethylphenylsulfate* (Figure 1d). This compound is made from the amino acid tyrosine by certain gut microbiota. When administered alone, it induces anxiety-like behavior in normal mice.¹ However, a remarkable finding is the ability to ameliorate defects in communication, anxiety, 4-ethylphenylsulfate levels, and gut permeability by feeding the affected mice a human gut commensal bacterium, either *Bacteroides fragilis* or *Bacteroides thetaiotaomicron* (Figure 1c). It is thought that these organisms displace the 4-ethylphenylsulfate producers and return gut chemistry to normal.

These studies offer an example of the importance of the gut microbiota–brain

connection in behavior and point to the possibility of modifying the gut community, such as might be possible with targeted probiotic therapy (Section 24.12), to alleviate symptoms in human neurodevelopmental disorders such as autism. Furthermore, amelioration of aberrant behavior by reducing serum levels of the gut microbiota–derived metabolite 4-ethylphenylsulfate to normal levels suggests that other neurodevelopmental illnesses may also be linked to the accumulation

of microbial metabolites in serum by an unbalanced gut microbiota. However, one must be cautious about overinterpreting this study because the science thus far is only at the early stages of associating the gut microbiota with behavioral disorders.

24.3 Oral Cavity and Airways

Mucous membranes throughout the body support the growth of a normal microbiota that helps prevent infection by pathogenic microorganisms. Mucous membranes consist of epithelial cells, tightly packed cells that interface with the external environment, and are found throughout the body, lining the urogenital, respiratory, and gastrointestinal tracts (Figure 24.5). Mucous membranes secrete *mucin*, forming the mucus layer that retains moisture and inhibits microbial attachment; invaders are usually swept away by physical processes like swallowing or sneezing, but some microorganisms adhere to the epithelial surface and colonize it. Here we discuss two mucosal environments and their resident microbes. In Chapter 25 we explore the mechanism of specific attachment of microbes to mucous membranes leading to growth and development of the normal microbiota or, alternatively, to microbial disease.

Figure 24.7 Bacterial diversity of saliva. The results are pooled analyses of approximately 750,000 sequences (from 159 samples) of the V1–V3 region of the 16S rRNA gene (◀ Figure 13.24). Note the lower fraction of anaerobes affiliated with *Fusobacteria* and *Spirochaetes* relative to the distribution of taxa observed in subgingival plaque (Figure 24.11). Many of these groups are discussed in Chapters 15 and 16. Data assembled and analyzed by Nicolas Pinel.

Oral Microbial Diversity

The complex mixture of nutrients present in the mouth is supplied by saliva (containing proteins, glycoproteins, amino acids, peptides, and vitamins) and the ingestion of food. This nourishes a diverse community comprised of both aerobes and anaerobes. However, saliva itself is not a good microbial growth medium because saliva contains antibacterial substances. These include *lysozyme*, an enzyme that cleaves glycosidic linkages in peptidoglycan of the bacterial cell wall, weakening the wall and causing cell lysis. Another enzyme, *lactoperoxidase*, found in both milk and saliva, kills bacteria by a reaction that generates singlet oxygen (a toxic form of oxygen, ▶ Section 4.16). Despite the activity of these antibacterial substances, food particles and cell debris provide high concentrations of nutrients near surfaces such as the teeth and gums, creating favorable conditions for extensive local microbial growth that can contribute to tissue damage and disease.

The oral cavity provides a variety of microbial habitats, each colonized by species that grow primarily as biofilms (▶ Sections 4.9, 8.10, and 20.4). The microbiota in saliva consists of microorganisms shedding from multiple sites within the oral cavity and provides an overview of oral microbial diversity (Figure 24.7). The oral microbiome is essentially as diverse as that of the gut, but human populations share greater proportions of common taxa for the mouth than for the gut. Almost all of the microorganisms inhabiting the healthy oral cavity can be assigned to seven bacterial phyla: *Firmicutes*, *Proteobacteria*, *Bacteroidetes*, *Actinobacteria*, *Fusobacteria*, *Saccharibacteria*, and *Spirochaetes*.

At least 750 species of aerobic and anaerobic microbes, including a minor representation of methanogenic *Archaea* and yeast, reside in the human oral cavity, distributed among teeth, tissue surfaces, and saliva. Most of these microorganisms have facultatively aerobic metabolisms, but some, such as *Bacteroidetes* and *Spirochaetes*, are obligately anaerobic. A few have strictly aerobic metabolisms, such as species of *Neisseria*, *Campylobacter*, and *Haemophilus* (a member of the *Pasteurellaceae*) in the *Proteobacteria* phylum. The most abundant genera are *Firmicutes*, major degraders of polysaccharides derived from the host or diet. Among *Firmicutes*, *Streptococcus* (~20%) and the obligately anaerobic *Veillonella* (~9%) are most abundant, although their relative numbers vary greatly as a function of oral cleanliness. Acid-producing, carbohydrate-fermenting genera physiologically and morphologically similar to the streptococci are also common *Firmicutes*, including species of *Abiotrophia* (*Aerococcaceae*), *Gemella* (*Gemellaceae*), and *Granulicatella* (*Carnobacteriaceae*).

Nanosynbacter lyticus is the first described species of the phylum *Saccharibacteria* (Figure 24.7) and is unique among oral bacteria (Figure 24.8). *N. lyticus* is a member of the ultrasmall (200–300 nm) bacterial radiation first observed in the terrestrial subsurface (▶ Section 20.8 and Explore the Microbial World, “Tiny Cells” in Chapter 1). This

Figure 24.8 *Nanosynbacter lyticus*. The epiparasite *N. lyticus* is a species of the phylum *Saccharibacteria*. The tight physical association between *N. lyticus* cells (arrows) and its host *Actinomyces odontolyticus* is shown in (a) a transmission electron micrograph of a thin section, and (b) fluorescence in situ hybridization (FISH, ◀ Section 19.5) imaging of intact cells (red *N. lyticus* cells attached to white *Actinomyces* filaments). An *N. lyticus* cell is about 250 nm in diameter.

diminutive bacterium has a highly reduced genome and lacks the ability to synthesize any amino acid, vitamin, or cell wall precursor. It exists as an obligate epiparasite, drawing nutrients from other oral bacteria by physical attaching to them. Lactate, a major metabolic product of oral streptococci, seems to be an important carbon and energy source for *N. lyticus*, as assessed from genomic analysis of cultured *N. lyticus* cells grown with oral actinobacteria as host (Figure 24.8). A similar symbiotic relationship occurs in the *Archaea* where the tiny parasitic and hyperthermophilic *Nanoarchaeum equitans* grows attached to the surface of cells of *Ignicoccus* (◀ Section 17.6 and Figure 17.17).

Figure 24.9 Section through a tooth. The diagram shows the tooth architecture and the surrounding tissues that anchor the tooth in the gum.

Oral Microenvironments and Their Microbiota

Bacteria found in the mouth during the first year of human life (when teeth are absent) are predominantly aerotolerant anaerobes such as streptococci and lactobacilli, and a few aerobes. When the teeth appear, the newly created surfaces are rapidly colonized by aerotolerant and obligate anaerobes that are specifically adapted to growth in biofilms on the surfaces of the teeth and in the gingival crevices (Figure 24.9). The formation of biofilms on teeth (*dental plaque*) is an ordered process of microbial assembly, where order is determined by highly specific binding between cell surface adhesins of one species and specific receptors on another species. *Streptococcus* and *Actinomyces* are the pioneer colonizers of a freshly cleaned tooth surface, followed by successive adherence by species of *Veillonella*, *Prevotella*, *Fusobacterium*, and other genera. The highly ordered structure can be revealed using fluorescence microscopy to visualize the layers of different genera in plaque (Figure 24.10). Close physical proximity may serve the function of metabolic cooperation. For example, *Veillonella* and *Streptococcus* establish a close physical and

Figure 24.10 Structured microbial community of dental plaque. Organization of different bacterial genera in a thin section through human dental plaque visualized by fluorescence in situ hybridization (FISH, ◀ Section 19.5). The micrograph shows streptococci (stained green) located primarily at the periphery of the plaque beyond several other genera that combine to form a scaffold emerging from the tooth surface. These include early-colonizing *Corynebacterium* spp. (purple) near the tooth surface, covered by later-colonizing fusobacteria (*Fusobacterium*, yellow; *Leptotrichia*, blue-green), and capped by species of *Capnocytophaga* (red), *Streptococcus* (green), and *Haemophilus* (orange) in this highly organized assembly.

Figure 24.11 Bacterial diversity of subgingival plaque. The results are pooled analyses of approximately one million sequences (from 183 samples) of the V1–V3 region of the 16S rRNA gene (◀ Figure 13.24). Compare the fractional distribution of different bacterial taxa with that observed in saliva (Figure 24.7), noting the higher representation of anaerobic fusobacteria and spirochete populations in the oxygen-limited gingival crevice. Many of these groups are discussed in Chapters 15 and 16. Data assembled and analyzed by Nicolas Pinel.

metabolic association in which the *Veillonella* consumes the lactate produced by streptococcal fermentation of carbohydrates.

Most of these bacteria contribute to the health of the host by keeping pathogenic bacteria in check and preventing them from gaining access to mucosal surfaces. Tooth decay, gum inflammation, and periodontal disease are among the most visible manifestations of a breakdown in these generally stable mutualisms. We discuss the microorganisms associated with the hard tooth surface and their contribution to the formation of dental plaque and dental caries in Section 25.2.

There is significant site variation in the diversity and specificity of colonization by different oral bacterial species. For example, there are differences in abundant microbial taxa associated with subgingival plaque (plaque that forms under the gums) (Figure 24.11) compared with that found in saliva (Figure 24.7). Compare Figure 24.7 and Figure 24.11 and note the greater representation by *Actinobacteria* and *Spirochaetes* in the subgingival plaque. Different species of *Corynebacterium* (a genus of the *Actinobacteria*, ▶ Section 16.10) demonstrate significant site specificity. For instance, *Corynebacterium matruchotii* is almost exclusively found in the supragingival plaque, whereas *Corynebacterium argentoratense* occurs mostly in the saliva. *Lautropia mirabilis* (*Proteobacteria*) selectively colonizes the supragingival plaque, whereas the spirochete *Treponema socranskii* is found mostly in subgingival plaque, presumably because this site provides the low-oxygen environment needed for microaerobic growth of this bacterium. The distribution of *Firmicutes*, *Proteobacteria*, and

Bacteroidetes is similar between the oropharynx (see Figure 24.12) and saliva. The hard palate (roof of the mouth) harbors a much lower diversity of microbiota than does the gingival plaque, possibly as a result of constant shedding of epithelial cells and the shear forces associated with chewing and swallowing.

Microenvironments of the Respiratory Tract

The anatomy of the respiratory tract is shown in Figure 24.12 and Figure 24.1. In the **upper respiratory tract** (including the sinuses, nasal and oral cavities, and throat—pharynx, tonsils, and larynx), microbes live bathed in secretions from the mucous membranes. Bacteria continually enter the upper respiratory tract from the air during breathing, but most are trapped in the mucus of the nasal and oral passages and expelled with nasal secretions or swallowed and then killed by the acid in the stomach. However, a few microbes colonize respiratory mucosal surfaces in all individuals; those most commonly present are species of staphylococci, streptococci, diphtheroid bacilli, and gram-negative cocci.

Occasionally, potential pathogens such as *Staphylococcus aureus* and *Streptococcus pneumoniae* are part of the normal microbiota in

Figure 24.12 The respiratory tract. In healthy individuals the upper respiratory tract has a large variety and number of microorganisms. By contrast, the lower respiratory tract in a healthy person has few microorganisms.

Mastering

The respiratory
tract

the nasopharynx of healthy individuals. These individuals are *carriers* of the pathogens but do not normally develop disease, presumably because the other resident microorganisms compete successfully for nutritional and metabolic resources and limit pathogen attachment, colonization, or activities. The innate immune system (Chapter 26) and components of the adaptive immune system such as secreted antibodies (Chapter 27) are particularly active at mucosal surfaces and inhibit growth and invasion by potential pathogens.

The **lower respiratory tract** (trachea, bronchi, and lungs, Figure 24.12) has no naturally resident microbiota in healthy adults, but does harbor very low numbers of bacteria (primarily *Prevotella*, *Veillonella*, and *Streptococcus*) that are introduced from the upper respiratory tract during normal breathing. Dust particles, which are fairly large, settle in the upper respiratory tract. As the air passes into the lower respiratory tract, the flow rate decreases, and organisms settle onto the walls of the respiratory passages. The walls of the entire respiratory tract are lined with ciliated epithelial cells, and the cilia, beating upward, push bacteria and other particulate matter toward the upper respiratory tract where they are then expelled in saliva and nasal secretions or are swallowed. Only particles smaller than about 10 μm in diameter reach the lungs. Nevertheless, these include some pathogenic microbes, most notably certain bacteria and viruses that cause pneumonia (inflammation of the lungs, ► Sections 31.1, 31.2, and 31.8).

We now leave the oral cavity and explore the microbial diversity of other potentially heavily colonized body sites, the urogenital system and the surface of the skin.

Check Your Understanding

- Compare the microbial microenvironments in the oral cavity in newborns and adults.
- Identify the major microbes that predominate in the adult oral cavity by taxa and metabolic requirements.
- Why is the lower respiratory tract typically microbe-free?

II • Urogenital Tract and Skin Microbiomes and the Human Viral Microbiome

A resilient lactobacilli community colonizes the healthy vagina and maintains a weakly acidic environment. Different oily, moist, and dry microenvironments of healthy skin select for different distributions of primarily gram-positive bacteria. The human viral microbiome (virome) consists of both animal viruses and bacteriophages.

24.4 Urogenital Tracts and Their Microbes

In the urogenital tracts of healthy adults (Figure 24.13), the kidneys and bladder are believed to be sterile; however, facultatively aerobic gram-negative bacteria colonize epithelial cells lining the distal

(a)

(b)

Figure 24.13 Microbial growth in the urogenital tracts. (a) The urogenital tracts of the human female and male, showing regions (red) where microorganisms often grow. The upper regions of the urogenital tracts of both males and females are sterile in healthy individuals. (b) Gram stain of *Lactobacillus acidophilus*, the predominant organism in the vagina of women between the onset of puberty and the end of menopause. The individual gram-positive rods are 3–4 μm long. Species of *Lactobacillus* are anaerobic bacteria that ferment glucose and other sugars primarily to lactic acid as a fermentation product (► Section 16.6).

urethra, and the bladder of even healthy individuals may harbor a resident microbial community similar in composition to that of the urethra. Potential pathogens such as *Escherichia coli* and *Proteus mirabilis*, normally present in small numbers in the body or in the local environment, can multiply in the urethra and cause disease if conditions such as changes in pH occur. Such organisms are a frequent cause of urinary tract infections, especially in females. *Proteus* is especially notorious as a urinary tract pathogen. This bacterium is a strong urease producer; it generates ammonia from urea and uses the ammonia as a nitrogen source. Ammonia also causes urine pH to become quite alkaline, and this can trigger other urinary tract conditions such as the formation of kidney stones.

The vagina of the adult female is weakly acidic (pH ~5) and contains significant amounts of glycogen. *Lactobacillus acidophilus*, a resident organism in the vagina, ferments the polysaccharide glycogen, producing lactic acid that maintains a local acidic environment (Figure 24.13b). Other organisms, such as species of the yeasts *Torulopsis* and *Candida*, various streptococci, and *E. coli*, may also be present. Before puberty, *L. acidophilus* is absent, the female vagina is neutral in pH and does not produce glycogen, and the microbiota consists predominantly of staphylococci, streptococci, corynebacteria, and *E. coli*. After menopause, glycogen production ceases, the pH rises, and the microbiota again resembles that found before puberty.

Metagenomic 16S rRNA sequence analyses have confirmed earlier culture-based observations that the vaginal microbial community is less complex at the genus level than the oral or gut communities. A healthy vaginal microenvironment is dominated by lactobacilli (Figures 24.1 and 24.13b) and *vaginosis* (major changes in the balance of microbes in the vagina) is characterized by increased bacterial diversity, elevated pH, and a vaginal discharge. But even in the healthy adult female, vaginal microbiota consists of over 100 bacterial genera that group into several primarily gram-positive bacterial families (Figure 24.14).

There are at least five types of “normal vaginal communities” containing different compositions of *Lactobacillus* spp., the dominant gram-positive organisms in the vagina. Four types are defined by

dominance by one of *L. crispatus*, *L. iners*, *L. reuteri*, or *L. jensenii* (see also Figure 24.27), while the fifth is a more heterogeneous type characterized by higher overall diversity and a greater proportion of other strict anaerobes relative to the lactobacilli. Although all vaginal community types are associated with an acidic pH, pH varies with community type. The *L. crispatus* type shows the lowest average pH (~4.0), whereas the heterogeneous type shows the highest average pH (~5.3).

Thus, unlike the picture of microbial diversity we have seen in the gut or the oral cavity, the microbiota in the vagina of the healthy female is overwhelmingly dominated by lactobacilli (Figure 24.14). In contrast to the vagina, studies of the penis microbiota are fewer, but the general picture shows that the bacterial diversity of the penis is similar to that in the vagina, the patterns being especially so in sexual partners. Species of *Lactobacillus*, *Streptococcus*, and *Sneathia* are commonly found in both the male and female urethra. However, the microbiota on the circumcised versus the uncircumcised penis can be quite different, and bacterial abundance on the uncircumcised penis is typically much greater as well.

Check Your Understanding

- What is the importance of vaginal *Lactobacillus* in healthy adult women?
- What variable feature of the vagina is most closely associated with different community compositions of *Lactobacillus* species?

24.5 The Skin and Its Microbes

The skin is a complex human organ functioning primarily to prevent loss of moisture and restrict the entry of pathogens. An average adult human has about two square meters (2 m²) of skin surface that varies greatly in chemical composition and moisture content. Skin also provides an environment for part of the human microbiome. The skin microbiota consists of a rich community of microorganisms that associates intimately with the host's hormonal, nervous, and immunological systems.

There are approximately 1 million resident bacteria per square centimeter of skin, for a total of about 10¹⁰ skin microorganisms covering the average adult. Although these numbers are much lower than the oral and gut communities, molecular analyses have shown that the skin harbors a diverse microbial community of bacteria and fungi (primarily yeast) that varies significantly with location on the body as a function of the diversity of habitats. These habitats consist of microenvironments of varying temperature, pH, moisture, sebum content (sebum is the oily secretions of the sebaceous glands), and surface characteristics. One distinct set of microenvironments includes moist skin areas such as the inside of the nostril, the armpit, and

Figure 24.14 Vaginal bacterial diversity. The results are pooled analyses of approximately 600,000 sequences (from 86 samples) of the V1–V3 region of the 16S rRNA gene (◀ Figure 13.24). Note the dominant fractional representation by *Lactobacillus* species and related *Firmicutes*, as compared to the diversity found at other body sites. Many of these groups are covered in Chapters 15 and 16. Data assembled and analyzed by Nicolas Pineda.

(b)

Figure 24.15 Overview of the skin microbiota. (a) Analysis of the skin microbiome from 10 healthy human volunteers detected 19 bacterial phyla. Four phyla were predominant. (b) Composite populations of *Bacteria* from the same volunteers, divided according to sebaceous, moist, and dry skin microenvironments. Data adapted from Grice, E.A., et al. 2009. *Science* 324: 1190.

the umbilicus. Moist skin is separated by only a few centimeters from dry microenvironments such as the forearms and the palms of the hands. A third microenvironment consists of areas with high concentrations of sebaceous glands such as those by the side of the nose, the back of the scalp, and the upper chest and back. In addition to these

site-specific differences, sweat is high in salt and other antimicrobial substances such as free fatty acids and antimicrobial peptides and thus plays a role in controlling diversity.

Microbial Diversity of Skin Microenvironments

A 16S rRNA sequencing comparison of 20 diverse skin sites categorized as moist, dry, or oily revealed tremendous diversity and variation among sites and individuals and also showed some common patterns (Figure 24.15). Collectively, nearly 20 bacterial phyla were detected, but most phylotypes affiliated with one of four groups: *Actinobacteria* (~52%), *Firmicutes* (~24%), *Proteobacteria* (~16%), and *Bacteroidetes* (~6%). Over 200 different genera were identified, but species of three genera, *Corynebacterium* and *Propionibacterium* (both *Actinobacteria*) and *Staphylococcus* (*Firmicutes*) typically dominated the observed phylotypes (Figure 24.15b).

Each skin microenvironment showed a unique microbiota. Moist sites are dominated by corynebacteria and staphylococci, while drier sites support a mixed population dominated by *Betaproteobacteria*, corynebacteria, and *Flavobacteriales*. Species of *Propionibacterium* predominate in sebaceous areas (Figure 24.15b). For example, colonization of the follicular sebaceous gland system by *Propionibacterium acnes* is promoted by its ability to hydrolyze triglycerides present in sebum, resulting in release of free fatty acids that promote adherence of this bacterium, which sometimes causes disease (acne, Section 24.10).

A higher-resolution molecular diversity study of 400 different body sites of one male and one female subject revealed 850 distinct species, as bacterial species are currently defined (Section 13.12). The results of a high-resolution analysis of a single dry skin site (the inside of the elbow) are shown in Figure 24.16. As shown by the more general studies (Figure 24.15a), the most common microbial phyla were *Actinobacteria*, *Firmicutes*, *Proteobacteria*, and *Bacteroidetes*, but in this work, the breakdown of each phylum into family-level taxa shows a significant hidden diversity within each major group. Although staphylococci, propionibacteria, and *Betaproteobacteria* dominate, many other groups are also present (Figure 24.16).

The abundance of specific bacterial taxa can also be visualized in a “heat map” diagram (Section 10.10 and Figure 10.28) showing the major locations of different taxa on the skin. An example is shown in Figure 24.17 where it can be seen that *Propionibacterium* tends to localize on sebaceous regions (head, face, upper back, and upper chest), whereas species of *Staphylococcus* and *Corynebacterium* are more prevalent on less exposed regions, such as the groin, armpit, and toe web—areas higher in temperature and moisture content (Figure 24.17).

Other Aspects of the Skin Microbiome

Eukaryotic microbes and *Archaea* are also present on the skin. The yeast *Malassezia* is the most common fungus found on the skin, and at least five different species of this yeast are typically present on the skin of healthy individuals. In an individual with a weakened immune system, for example, someone who has HIV/AIDS or whose normal microbiota has been compromised, *Candida* and other potentially pathogenic fungi can also colonize the skin and cause serious (even fatal) infections (fungal pathogens are discussed in Chapter 34). A remarkable finding emerging from 16S rRNA gene surveys of skin is that ammonia-oxidizing *Archaea* (Section 17.5)

Figure 24.16 Skin bacterial diversity at the inside of the elbow. Note that *Propionibacterium* species comprise the vast majority of the *Actinobacteria*, and that *Staphylococcus* species dominate skin-associated *Firmicutes*. The results are pooled analyses of approximately 80,000 sequences (from 123 samples) of the V1–V3 region of the 16S rRNA gene (◀ Figure 13.24). Many of these groups are discussed in Chapters 15 and 16. Data assembled and analyzed by Nicolas Pintel.

can comprise as much as 4% of the skin microbiota in some individuals, presumably sustained by ammonia present in the sweat of more physically active individuals.

Environmental and host factors influence the composition of the normal skin microbiota. For example, the *weather* may cause an increase in skin temperature and moisture, which increases the abundance of the skin microbiota. The *age* of the host also has an effect; young children have a more varied skin microbiota and carry more potentially pathogenic gram-negative *Bacteria* than do adults. *Personal hygiene* also greatly influences the resident skin microbiota; individuals with poor hygiene typically have higher microbial population densities on their skin. And finally, many microorganisms that would otherwise colonize skin cannot survive there simply because of its low moisture content and presence of antimicrobial fatty acids. Thus, the skin is a natural barrier to microbial colonization (▶ Figure 26.2) while at the same time supporting a diverse array of normal microbiota.

As yet, there have been no significant longitudinal studies of early colonization and succession of the skin microbiome as have been conducted for the gut microbiome (Section 24.8). However, it is well recognized that the skin microbiome undergoes a major transition associated with sexual maturation. The skin of young children is dominated by *Streptococcus* spp., *Betaproteobacteria*, and *Gammaproteobacteria*. By contrast, these taxa are largely absent from the skin of postadolescent young adults; in this group the skin is characteristically dominated by species of *Propionibacterium* and *Corynebacterium*, as we have seen (Figures 24.15 and 24.17). And finally, encounters

with man's best friend can contribute to the human skin microbiota. Studies have shown that adult dog owners have more skin microbes in common with their own dogs than with other dogs. This demonstrates that close and regular contact between two distinctly different species of animal can result in a major sharing of their microbiomes. In contrast to the skin microbiota, microbes in the mouths and guts of canines differ quite distinctly from those of their owners.

Check Your Understanding

- Compare the populations of microorganisms in the three major skin microenvironments.
- Describe the properties of microorganisms that grow well on the skin.

24.6 The Human Virome

In Chapter 5 we highlighted the infection process of animal viruses, and we described the general morphology and genomic structure of common animal viruses in Chapter 11 (◀ Figures 11.2 and 11.3). Animal viruses differ from bacteriophages and archaeal viruses in that an animal cell takes up the *entire virion* instead of just the viral genome. There are also more than two lifestyles for animal viruses, including virulent infection, latent infection, persistent infection, and cellular transformation (◀ Figure 5.22). A healthy human is teeming with viruses—not just animal viruses but also bacteriophages and possibly even some plant viruses—and we examine this suite of viruses now.

Figure 24.17 Distributions of *Staphylococcus*, *Propionibacterium*, and *Corynebacterium* on the human skin. Heat maps of microbial species distributions at 400 different body sites inferred from 16S rRNA gene sequences from the skin of male (top) and female (bottom) subjects (in scale bar, red indicates higher relative abundance and blue lower abundance). *Propionibacterium* species tend to localize on sebaceous regions (head, face, upper back, and upper chest); *Corynebacterium* species are most common on the head, groin, and toes; and *Staphylococcus* species are most abundant on the foot.

Amina Bouslimani and Pieter Dorrestein

The Human Body and the Virome

While profiling the viruses of the human body has been hampered by limitations in cell culturing, the power of metagenomics has not only allowed for the human *microbiome* to be characterized (Section 24.1), but also the human **virome**. The human virome encompasses the entire population of viruses present in and on the human body (Figure 24.18). And, as for the human microbiome, the human virome is both unique to an individual and relatively stable over long periods.

Depending on the individual, animal viruses of the human virome include those that cause severe diseases such as hepatitis and severe acute respiratory syndrome, those that cause milder acute infections such as influenza and viruses of the common cold, and those that are completely benign. Other common animal viruses of the human virome cause latent infections, such as the herpesviruses, in particular human cytomegalovirus, present in most human adults (the biology of these viruses is covered in Chapter 11 and the disease syndromes themselves in Chapters 31–33).

Viruses that contain DNA genomes dominate the viromes of healthy humans. Areas of the human body in which the virome has been assessed are the nose, skin, mouth, and gastrointestinal tract (from fecal samples). Animal viruses commonly detected in these areas include the single-stranded DNA anelloviruses and circoviruses and the double-stranded DNA adenoviruses, polyomaviruses, and papillomaviruses (Figure 24.18a). Anelloviruses are nonenveloped viruses that establish persistent infections in the body early in life with no known connection to disease. Circoviruses possess some of the smallest of all viral genomes and are commonly found in poultry and pigs, suggesting that their presence in the human gastrointestinal tract may originate from these food sources.

Adenoviruses are common respiratory viruses that have been detected in children with fevers but are also found in the nose and upper

respiratory tract of healthy humans. Similarly, polyomaviruses are commonly found in healthy individuals, but in immunocompromised individuals they can also cause urinary tract infections and a type of brain disorder called *leukoencephalopathy*. Several different papillomaviruses are also common in the human virome, especially in the skin and saliva. *Papillomaviruses* are non-enveloped double-stranded DNA viruses (Baltimore class I, ◀ Figure 11.2) that replicate on skin and in mucosal epithelia of virtually all mammals. Most papillomavirus infections are asymptomatic; however, the human papillomavirus (HPV) causes persistent infections that can develop into skin warts, and certain strains of HPV can cause premalignant lesions in the female reproductive tract that can lead to cervical cancer later in life. Nearly all cervical cancers are attributed to HPV, and this virus also causes many cancers of the vagina, vulva, penis, anus, and oropharynx.

Besides these common animal viruses, most human viromes also contain viruses that infect plants, such as the pepper mild mottle virus (Figure 24.18a). These viruses are undoubtedly transmitted to humans from foods and pass through the intestines. While the host specificity of these viruses is for plants, it is thought that their presence in humans may trigger inflammation, which may lead to some of the symptoms susceptible individuals have to spicy foods or certain plant products. Another possible interaction between the human virome and the immune system is the prevalence of *human endogenous retrovirus* (HERV) elements in human chromosomes; HERVs are remnants of retroviral genes that have been incorporated into and constitute 5–8% of the human genome. Although most HERVs are thought to be harmless, connections have been proposed between certain HERVs and the autoimmune disorders rheumatoid arthritis and systemic lupus erythematosus (▶ Section 28.1), and with other afflictions such as inflammatory bowel (Crohn’s) disease and multiple sclerosis.

Bacteriophages and the Human Virome

While every human body contains a unique mixture of different animal viruses, the most abundant viruses in all body sites are not animal viruses but instead are bacteriophages. The large intestine is a hotbed for such viruses, as this organ contains an abundance of prokaryotic cells and virions (numbering about 10^{11} and 10^9 , respectively, per gram of feces). However, unlike the marine virosphere (◀ Section 20.13), for example, in which bacteriophage virions greatly outnumber bacteria, the virion to microbe ratio (VMR)

Figure 24.18 The human virome. (a) Common viruses of eukaryotes found in the virome of a healthy human. (b) Bacteriophages within the mucosa of the human respiratory and gastrointestinal tracts protect epithelial cells from the invasion of bacterial pathogens. (c) Movement of T4 bacteriophages in mucus. Tracks represent movement of fluorescently labeled individual bacteriophage virions within a microfluidic chip containing 1% mucin to simulate the mucus environment shown in part b.

in the gut is much lower and could be as low as one virus for every 100 bacteria. As with the animal viruses of the human virome, DNA bacteriophages dominate, and many of these viruses are thought to benefit bacterial cells by transferring genes encoding antibiotic resistance or enzymes for specialized metabolisms through the genetic transfer processes of transduction (◀ Section 9.7) and lysogeny (◀ Section 5.6).

A unique feature of the gut virome is that most bacteriophages are in a lysogenic state, reproducing in concert with their host bacterium and therefore persisting for prolonged periods. Observations of bacteriophage diversity within an individual have shown it to be remarkably stable, with 80–95% of bacteriophages retained for over 2 years, and likely for much longer. Persistence and stability likely derive from the stability of the bacterial community (see Section 24.8) and a preference for the bacteriophage to enter into a stable lysogenic state. Thus, although genetic transfers from gut bacteriophages to their hosts likely help the gut microbiota adapt to changing nutrient conditions and stabilize it from the stresses of antibiotic treatment, the mechanisms and frequency of exchange may be quite different in the gut than in open environmental systems.

Metagenomic surveys of DNA recovered from virions separated from feces have shown that between 75% and 99% of bacteriophages in the gut microbiome are not closely related to known viral genomes. Thus, matching bacteriophage genomes with the bacterial hosts they infect is a daunting challenge. Even so, important progress has been made in identifying novel bacteriophages by matching CRISPR sequences (◀ Section 9.12) between phage and bacterial genomes to search for links in a virus–host association. Using this strategy, the isolation of a major group of novel tailed bacteriophages (called *crAssphage*) present in at least half of the human

population was achieved by recovering the bacteriophage on cultures of the *Bacteroides* species predicted by metagenomic sequencing to serve as its host (see MicrobiologyNow on page 819).

Function of the Human Virome

Why are there so many bacteriophages in and on us? Probably because our bodies are home to such enormous levels of bacteria. To our benefit, phages likely play a protective role in human health. Bacteriophages of the human virome can be a first line of defense against certain pathogens, especially within mucosal surfaces where bacteriophages accumulate. It has been estimated that 20 times more bacteriophages than bacteria exist in the mucosa of our lungs and intestines. The bacteriophages present in mucous linings are anchored to sugar residues produced by mucosal cells (Figure 24.18b). Here bacteriophages presumably scavenge invading pathogens and kill them before they can cross the mucous barrier. Thus, phages within the mucus layer can be considered to have a symbiotic relationship with the human host and provide a form of host-independent immunity. Using fluorescently labeled T4 phages, movement of the phages through a model mucus layer can actually be tracked microscopically in the laboratory (Figure 24.18c).

Besides killing or conferring antibiotic resistance to bacteria within the microbiome, the bacteriophage component of the virome can also *enhance* the pathogenicity of certain bacteria. An example of this is the lysogenic bacteriophage CTX ϕ and its host, the bacterium *Vibrio cholerae* (the bacterium that causes cholera). It is the phage genome rather than the host genome that actually encodes the cholera toxin that induces disease symptoms (▶ Section 33.3), and cells of *V. cholerae* that are not CTX ϕ lysogens are nonpathogenic. This

phage–bacterium link is also seen in the *toxin-coregulated pilus*, a structure essential for *V. cholerae* cells to attach to intestinal cells. Genes encoding the pilus are part of a viral genome that is integrated into the host's genome (a prophage, ◀ Section 5.6) and is only present in pathogenic strains of *V. cholerae*.

With recognition of the potentially huge impact on human health by the virome coupled with the continually improving field of metagenomics, we can expect to have a much clearer understanding of the role bacteriophages play in health and disease in the near future. Indeed, a handful of therapeutic bacteriophage treatments have already been developed for humans and shown to be effective (see MicrobiologyNow at the beginning of Chapter 5 and the MicrobiologyNow on page 819).

We now turn our attention to how the human microbiome first develops and the importance to human health of early exposure to the microbial world.

- What accounts for the remarkable stability of the gut virome?
- How do bacteriophages benefit and harm human hosts?

III • From Birth to Death: Development of the Human Microbiome

Different body sites of the newborn are rapidly colonized, receiving microbes from the mother and the local environment. A mature gut community takes about three years to develop and is greatly influenced by early life events. Each individual harbors a unique microbiome but one that can be altered by diet and aging.

At birth, a baby is exposed to both maternal and environmental microorganisms. These early encounters determine the composition of microorganisms that first colonize different body sites. In this part of the chapter we focus primarily on colonization of the gut, the body site harboring the largest part of the human microbiome, and consider factors that govern early colonization and subsequent successional events of a community now recognized to be critical to general health and the education of the immune system.

24.7 Human Study Groups and Animal Models

Establishing relationships between the composition of a person's microbiome and its contribution to health and disease has been complicated by problems surrounding sampling, the uncertainty about the contribution of the host's genetic background, and the limitations of controlling diet and other contributing lifestyle factors. Nevertheless, several human study groups and animal model experiments have revealed some of the basic principles and given microbiome studies a starting point.

Human Microbiome Study Groups

Most functional understanding of the human microbiome has been based on surveys of selected study groups (Table 24.1). For example, one of the most ambitious early studies was the Human Microbiome Project (HMP) funded by the U.S. National Institutes of Health. This study collected samples from 242 individuals (all American medical students in good health), sampling different body sites (15 to 18 sites depending on gender) at one to three time points, and then evaluated bacterial diversity based on 16S rRNA gene sequencing and limited metagenomic analyses (Figures 24.1 and 24.2).

The objective of the HMP was to develop baseline information about what constituted a “healthy” microbiome. Although the HMP generated a huge amount of data, the study group represented only a small fraction of human diversity. This limitation was clearly revealed in the Global Gut Project, which examined three distinct populations (U.S. citizens, Malawians, and a group of indigenous peoples from Venezuela) and different age groups within those populations. The gut microbiomes of the two non-U.S. populations were distinct from those of the U.S. individuals, showing that the HMP greatly underestimated the potential for variation in gut microbiomes across nationalities. These studies also suffered from a lack of appropriate metadata; for example, detailed information about dietary habits (vegetarian, vegan, omnivorous) and how much fiber or protein was ingested daily. Because there is still very limited understanding of the influence of specific environmental variables such as lifestyle, diet, gender, and genetics on microbiome structure and function, new and ongoing studies (e.g., the American Gut Project) are obtaining these valuable metadata at the time of sampling. The overarching goal is to develop robust correlations between the microbiome, host genetics, diet, lifestyle, health, and pathologies thought to have a microbial connection, in particular, heart disease, cancer, stroke, diabetes, and obesity.

Figure 24.19 Anatomy of the mouse and human intestinal tracts. The mouse (a) and human (b) intestinal tracts have significant structural differences that are associated with differences in the composition of the microbiota of mice and humans despite similarities in their physiologies.

The Mouse Model

Even if appropriate metadata are available, a major limitation of the human microbiome studies to date is establishing *causality*, something that is only possible with highly controlled animal studies. Hence the mouse has become the major model animal system for linking cause and effect in the gut microbiome.

Although the mouse and human digestive systems have some significant differences (Figure 24.19), the mouse (and to a more limited extent, the rat) has been the workhorse of experimental microbiome studies. Compared to humans, mice have a relatively larger colon and cecum, which are needed to extract nutrients derived primarily from the fermentation of plant materials. For example, the average ratio of the length of the murine small intestine to its colon is about 2.5 whereas in humans it is about 7. In mice, fermentation of plant material is compartmentalized in the cecum (◀ Section 23.14), while in humans this fermentation takes place in the colon. Nevertheless, mice have several experimental advantages, including the availability of well-defined genetic lines, low maintenance costs, and short life cycle. This has allowed researchers to explore the importance of the host genetic background through selective gene knockouts, the manipulation of gut microbiota composition using germ-free mice (raised free of all microbes), tests of the influence of a strictly controlled diet, assessing the consequences of antibiotic treatment, and exploring the transfer of physiological traits through fecal transplantation. These studies have clearly associated the composition of the mouse microbiome to different pathologies, including obesity and inflammatory bowel disease, as we will discuss in Section 24.9.

Unfortunately, because of anatomical differences (Figure 24.19), mouse studies are not directly applicable to humans, and these anatomical differences may in part account for observed differences in the relative abundance of dominant bacterial genera in mouse and human guts. For example, the genera *Prevotella*, *Faecalibacterium* (*Firmicutes*), and *Ruminococcus* are in high abundance in the human gut (Figure 24.6), whereas the genera *Lactobacillus*, *Alistipes*, and *Turicibacter* are more abundant in the mouse gut. Thus, although the mouse model gives us much experimental latitude not available in gut microbiome studies of humans, actual results from the two systems are not directly comparable. However, despite these differences in bacterial composition, experimenters have glimpsed much useful information from the study of animal models that has accelerated our understanding of the human gut microbiome (for example, see Section 24.9 and Figure 24.25).

We now follow development of the human gut microbiota from birth through adulthood, comparing and contrasting the major organisms seen in healthy humans. An overview of the mature and highly stable gut microbiota was presented in Figures 24.2, 24.3, and 24.6.

Check Your Understanding

- In hindsight, which aspects of the HMP were well controlled for and which were not?
- Why has it been so difficult to associate human disease, or health, with changes in the gut microbial community?
- What are some of the major differences between the mouse and human gastrointestinal systems?

24.8 Colonization, Succession, and Stability of the Gut Microbiota

Colonization of an initially sterile gut begins immediately after birth; a succession of microbial populations replace each other in turn until a relatively stable, adult microbial community is established. Colonization begins when the infant first encounters microbes by passage through the mother's vagina. The newborn is quickly inoculated by bacteria present in breast milk and skin, and later through contact with visitors and household pets.

The structure of the infant's gut community in the first year of life is highly dynamic and greatly influenced by early life events. In particular, birth by vaginal delivery versus cesarean section has a profound influence on early community structure. It is also now known that these early colonization events are critical to the microbe-immune system "cross talk" essential to the development of a well-functioning immune system. Disruption of a normal colonization sequence, such as may result from early-life treatment with antibiotics, is correlated with the development in later life of allergy and asthma, as well as type 1 diabetes and obesity. As we will review in Section 24.12, modulation of the developing gut community by early feeding of beneficial probiotic microorganisms is increasingly viewed as a means to avoid diseases associated with the early disturbance of the normal gut colonization sequence.

Microbial Community Structure and Function in the First Three Years of Life

The young infant gut community is dominated by bifidobacteria—fermentative anaerobes of the bacterial class *Actinobacteria* (◀ Section 16.10)—and does not reach an adultlike composition

Figure 24.20 Maturation of the infant gut community. Normal maturation of the breastfed infant's gut bacterial community during the first three years of life. *Bifidobacterium* and *Bacteroides* species are important early colonizers. As the gut community matures with termination of breastfeeding, species of *Firmicutes* (*Lachnospiraceae* and *Ruminococcaceae*) and *Bacteroidaceae* increase in relative abundance while *Enterobacteriaceae* decrease to very low levels.

until about age 3. The newborn's relatively simple community progressively evolves into a more complex and adultlike composition in these first three years. The first year is a period of tremendous fluctuation in community composition; the second year is a transitional phase and is followed by maturation to a stable, adultlike composition during year three.

Early microbial colonizers are an important source of amino acids and vitamins. Microbial genes encoding the synthesis of vitamins K₂ (menaquinone), B₆ (pyridoxal), and B₇ (biotin) are elevated in the newborn's microbiota. As the gut microbiome matures, there is a greater prevalence of microbial genes encoding synthesis of the vitamins B₁ (thiamine), B₅ (pantothenate), and B₁₂ (cobalamin). The immature gut community contains a large number of species affiliated with facultatively aerobic *Enterobacteriaceae* (Figure 24.20). The presence of bacterial genera such as *Escherichia* and *Enterococcus*, both facultative aerobes, in the newborn gut is also indicative of a more aerobic state of the early gut system and a greater role for the citric acid cycle and respiration in microbial energy production in the neonate.

Major factors controlling the early assembly of the gut microbiome following birth are whether birth was vaginal or by cesarean section (C-section) (Figure 24.21) and whether initial nutrition came from breast milk or from formula. A vaginally delivered infant is colonized by a gut microbiota similar to that of the mother, suggesting direct transfer from mother to neonate during passage through the birth canal and subsequent intimate contact with the mother. In contrast, the gut microbiota of a child delivered by C-section is significantly different from that of the mother. Approximately 70% of babies delivered vaginally develop a gut microbiome similar to their mothers, including species of *Escherichia* and *Bifidobacteria* (*Proteobacteria*), *Bifidobacterium* (*Actinobacteria*), *Enterococcus* (*Firmicutes*), and *Bacteroides*. By contrast, only about 40% of the species match those of the mother in the gut of a C-section neonate (Figure 24.21). The latter tends to be enriched in *Staphylococcus* and *Streptococcus* species (*Firmicutes*), and *Veillonella* species, indicating that skin and oral microbes, respectively, as well as environmental populations, were early colonizers. *Bacteroides* species are either less prevalent or totally missing in the infants delivered by C-section (Figure 24.21b). The difference in the gut microbiomes of babies born vaginally or by C-section is significantly less by 12 months of age, but the C-section gut microbial community at 8 months remains distinctive and more variable in composition than that of infants born vaginally (Figure 24.21).

The Microbiology of Breastfeeding versus Formula

Infants that have been breastfed develop a different gut microbiome than those who have not. Breastfeeding is associated with elevated numbers of fermentative *Bifidobacterium*, *Lactobacillus*, and *Staphylococcus* species. Viable populations of *Bifidobacterium* and *Lactobacillus* species are present in breast milk, and *Staphylococcus* species colonize the areolar skin. Thus, these species are transferred directly from mother to infant. *Staphylococcus epidermidis* is an opportunistic colonizer, essentially absent in formula-fed infants and an organism whose numbers decrease over time following cessation of breastfeeding.

The enrichment of *Bifidobacterium* species, in particular the species *B. longum*, is related to the composition of human milk. Breast milk contains a complex mixture of unusual oligosaccharides that most gut

Figure 24.21 Impact of birth mode on the young infant's gut community. Early colonization and temporal changes in the relative abundance of major microbial groups in children delivered (a) vaginally or (b) by cesarean section. With vaginal delivery, species of *Bacteroides* are present from an early age and *Proteobacteria* only poorly colonize. *Bacteroides* species are undetectable during the first 8–9 months of life following delivery by cesarean section, and a higher initial colonization by *Proteobacteria* persists throughout early life.

microbes (other than *Bifidobacterium* species) and humans are unable to digest; for example, the sugar monosialyl-lacto-*N*-neohexaose I (Figure 24.22). *B. longum* subspecies *infantis* is unique in having an exceptionally large repertoire of glycosidases and oligosaccharide transporters and grows well on this and other human milk oligosaccharides. These characteristics have also made this strain an important probiotic for treating enterocolitis in premature infants (see Section 24.12). With cessation of breast milk feeding and maturation of the infant gut microbiome, *B. longum* subspecies *infantis* is displaced by other strains of *B. longum* that can use both mammalian and plant-derived oligosaccharides. However, even with the introduction of solid food, the gut communities of infants that continue to receive some breast milk are less diverse than in those no longer getting breast milk. Thus, maturation of the gut microbiome is largely driven by the removal of breast milk from the diet—which generally occurs between 9 and 12 months—rather than by the introduction of solid foods.

At 4 months there remains a clear difference between children who have received exclusively breast milk compared with those given formula milk. Formula-fed infants tend to have elevated numbers of *Clostridioides difficile*—a potentially serious pathogen (► Section 30.7 and Figure 30.12)—as well as other potential pathogens such as *Citrobacter* and *Enterobacter*, whereas the guts of children that remain on breast milk at 12 months continue to be

Figure 24.22 Example of an oligosaccharide found in human breast milk. This and other short polysaccharides selectively nourish and enrich for desirable microbial populations, such as *Bifidobacterium* and *Lactobacillus* species, in the infant's developing gut microbial community.

dominated by *Bifidobacterium* and *Lactobacillus*. The abundance of *B. longum* in breastfed infants also leads to the production of short-chain fatty acids; this creates an environment favoring the growth of the normal microbiota important for “educating” the immune system. In addition, since the structures of human milk oligosaccharides mimic carbohydrates lining the infant gut, they function to suppress pathogenic bacterial infection by blocking the pathogens’ receptors for attachment. Therefore, in addition to providing nutrition to the newborn, breast milk selects for a specific group of earlier colonizing normal microbiota important to the overall health of the child and proper development of its immune system.

Termination of breastfeeding results in a shift of the community toward a more adultlike composition, as reflected by enrichment in *Bacteroides*, *Bifidobacteria*, *Roseburia*, *Clostridium*, *Anaerostipes*, and *Eikenella*. Many of these later-arriving genera are efficient degraders of dietary fibers and complex carbohydrates, consistent with a transition to more solid foods following the cessation of breastfeeding; they also produce short-chain fatty acids. The increased abundance of *Bacteroides thetaiotaomicron*, a bacterium encoding a diverse set of glycan-degrading enzymes, is specifically associated with the increase in pectin in solid foods. Although the development of a fully adultlike gut microbial community varies a bit from child to child, the average is three years.

Stability of the Adult Microbiome and Transitions with Age

Although metagenomic diversity studies have identified several thousand gut bacterial species, the number of species in any given individual is closer to 200, a number that remains stable for long

periods. The most stable of these species are typically affiliated with the *Bacteroidetes* and *Actinobacteria*. Although *Actinobacteria*, such as *Bifidobacterium* spp., comprise a rather small part of the adult gut microbiota compared to the *Bacteroidetes*, specific species tend to associate with individuals over long periods of time. By contrast, species of *Firmicutes* and *Proteobacteria* appear to be less stable members of the gut community. The species composition of the gut of an individual tends to reflect that of family members, and likely was established early in life. Thus, the early colonizers—including microbes acquired from parents or siblings—in large part determine the metabolic and immunological properties of the adult microbiome and may be an important factor in adult health and predisposition to disease.

As we age, so does our microbiome. The most well-established change is the age-related alteration in the relative proportions of *Firmicutes* and *Bacteroidetes*, with an increasing proportion of *Bacteroidetes* seen in the elderly as compared with the higher proportions of *Firmicutes* in young adults. Also observed with age are significant decreases in bifidobacteria and certain clostridial species. It also appears that the old age–related inability to perform routine daily activities, a measure of frailty, is correlated with decreased diversity in the gut microbiota. Consistent with this observation, elderly individuals living at home or in supportive communities have a more diverse gut community compared with those living in residential care facilities, such as nursing homes. Thus, maintaining a diverse gut microbiota is likely one of many links to health for the aged and is possibly even a positive effector of longevity.

With this overview of changes in the human microbiome with time, we move on to consider some startling discoveries about human diseases linked to unfavorable changes in the human gut microbiota. We then end this chapter by looking at some therapies for dealing with these problems.

Check Your Understanding

- What factors contribute to early colonization of the newborn’s gut community?
- How do microorganisms in the infant and adult gut community contribute differently to vitamin and amino acid requirements?
- What factor(s) are most important in the transition from an immature to a mature gut microbial community?

IV • Disorders Attributed to the Human Microbiome

Many major human health issues including obesity and inflammatory bowel disease correlate with disturbances of the microbiome. Maintenance of gut and general health depends on the continuous production of short-chain fatty acids by microbial fermentation of dietary fiber.

Alteration of the structure and activity of the human microbiome is associated with a variety of pathologies, including obesity, type 2 (non-insulin-dependent) diabetes, asthma, atopic dermatitis, liver disease, colorectal cancer, kidney stones, psoriasis, tooth decay

(dental caries), and periodontitis. As we learn more about the relationship between the human microbiome and health and disease, therapeutic intervention may well be possible. This might include promoting the growth of protective beneficial bacteria, inhibiting the growth of specific microbes (or specific assemblages of microbes) that compromise health, fecal transplants to introduce a desirable gut microbiota, and developing appropriate behavioral interventions, such as diet modification.

24.9 Syndromes Linked to the Gut Microbiota

A healthy gut community is loosely defined as constituting a relatively stable and resilient community associated with health of the human host. A gut microbial community demonstrating stability and resilience is said to be in a state of *homeostasis*. Variations from the homeostatic state may or may not trigger disease. We will first consider the healthy state and then explore some cases where alterations in the gut microbiome are strongly correlated with specific disease syndromes.

Diet and Gut Health

A specific definition of healthy homeostasis based on species composition has not been possible because individuals differ significantly in their specific gut community makeup, and community makeup shifts with diet. Thus, a healthy gut microbiota is increasingly being defined in dietary, metabolic, and immunological terms. Diet is a critical determinant of homeostasis. In particular, the **short-chain fatty acids** (SCFAs; primarily butyrate, propionate, and acetate) produced by fermentation of fiber by the gut microbiota serve a central role in the development and maintenance of a healthy gut. Not only are SCFAs an important energy source for intestinal cells, but they also function as signaling molecules to regulate cellular metabolism and immune surveillance (Figure 24.23). Binding of SCFAs to specific intestinal cell surface receptors regulates cellular metabolism, increases the secretion of antimicrobial peptides known as defensins (► Section 26.2), elevates production of hormones affecting energy recovery and sensations of hunger, and has a dampening effect on the inflammatory response through the regulatory T cell (Treg) signaling system (Figure 24.23 and ► Section 27.8).

Among SCFAs, butyrate in particular serves a critical function in the control of immune surveillance and the metabolism of colonocytes. Colonocytes are the absorptive epithelial cells of the large intestine (Figure 24.5). Butyrate activates a specific regulatory protein of colonocytes called PPAR- γ that accelerates mitochondrial beta-oxidation of fatty acids (◀ Section 14.23). This oxygen-consuming process helps to maintain an anoxic environment near the epithelial surface that is favorable to the obligately anaerobic bacteria that produce butyrate (Figure 24.23). If butyrate-producing microbes are depressed by, for example, a dramatic diet change or as a result of antibiotic treatment, colonocyte metabolism is shifted toward glucose fermentation and lower oxygen consumption. This results in greater passage of oxygen through the intestinal mucosal surface and a proliferation of facultatively aerobic bacteria (such as species of *Enterobacteriaceae*) that can invoke an inflammatory response. Since SCFA signaling also promotes tight junction formation (Figure 24.23), it is thought that a depression of PPAR- γ activity contributes to the development of *leaky*

gut syndrome in humans. Disruption of tight junctions leads to a greater exposure to gut microbiota, which in turn elicits an inflammatory response. Such a disruption of healthy gut function is called **dysbiosis**, typified by increased numbers of facultative aerobes, such as species of *Enterobacteriaceae*, and a state of chronic inflammation. These physiological changes are also thought to play important roles in the development of inflammatory bowel disease and obesity, and we turn our attention to these now.

Inflammatory Bowel Disease

The gut microbiota plays important roles in shaping the immune system in infancy; during this time, the normal microbiota and their products interact with immune cells to initiate and maintain host tolerance. The failure to develop tolerance to the normal microbiota early in life is associated with different immune-mediated diseases, including allergies and chronic inflammation of the gut such as *inflammatory bowel disease* (IBD).

It is widely accepted that IBD is not caused by a specific pathogenic microbe but rather an imbalance, or dysbiosis, between the immune system and the normal gut microbiota. The observation that antibiotic use in early life increases the risk of IBD points to the importance of the development of a normal gut microbiota in “educating” the immune system to differentiate between the normal

Figure 24.23 Role of short-chain fatty acids in intestinal health. Short-chain fatty acids (SCFAs) produced by microbial fermentation of fiber and dietary polysaccharides modulate the metabolic activity of colonocytes (see Figure 24.5) lining the intestinal epithelium. Butyrate activates the PPAR- γ regulatory protein, which then accelerates beta (β)-oxidation of fatty acids and the synthesis of tight junction proteins between cells and concurrently depresses colonocyte glycolysis. SCFAs also signal to regulatory T cells (Treg), suppressing the potential inflammatory response to normal gut microbiota. Together these shifts in metabolic activities reduce oxygen leakage into the lumen and maintain the integrity of the epithelial barrier.

microbiota and invading pathogens. For example, relative to healthy children, children with IBD have higher levels of species of *Veillonella*, *Prevotella*, *Lactobacillus*, and *Parasporobacterium* and lower levels of species of *Bifidobacterium* and *Verrucomicrobium*.

There is also evidence from mouse studies that once developed, IBD is transmissible. Fostering or co-caging healthy mice with IBD-predisposed mice was sufficient to cause IBD development in the healthy mice and was correlated with the transfer of the enteric bacterial species *Klebsiella pneumoniae* and *Proteus mirabilis* from the IBD mice to the healthy mice. In humans, metagenomic analyses of healthy subjects and patients with IBD shows that the gut microbiota of IBD patients shares fewer genes in common with healthy subjects, relative to the number of genes shared among healthy subjects. The microbial community of IBD patients also tends to have significantly reduced functional capacity, as reflected by a reduction in the number of nonredundant (functionally unique) genes relative to subjects that do not have IBD (Figure 24.24).

The mechanism of IBD formation is unclear but may be the result of disruption of mucosal barrier integrity (leaky gut) by a gut pathogen or a toxic insult, permitting commensal bacteria to interact with and activate the adaptive immune system (Chapter 27). This stimulates the proliferation and differentiation of T cells into commensal-specific effector cells that can persist in the intestine long after resolution of the infection. For example, the IBD syndromes of *Crohn's disease* and *ulcerative colitis* are known to be associated with a T cell response to intestinal commensal bacteria.

There is also a strong correlation between IBD and diet. With the typical Western diet rich in animal protein, carbohydrates are first fermented in the upper colon (Figure 24.3). As digesta move further along the colon, protein and amino acids are then fermented, generating potentially harmful metabolites such as ammonia, phenols, trimethylamine (TMA), and hydrogen sulfide (H₂S) that have been implicated in promoting IBD as well as playing a role in colon cancer. Animal studies have shown that these compounds can promote the development of a leaky gut and gut inflammation, as well as cardiovascular disease (CVD). TMA is converted to trimethylamine oxide (TMAO) in the liver, and TMAO contributes to coronary thrombosis by increasing blood platelet hyperresponsiveness. A high concentration of TMA accelerates atherosclerosis (clogging and stiffening of the arteries) development in mice and is correlated with a higher incidence of CVD in humans. In contrast, a diet rich in plant-based foods (high fiber) works against development of these pathologies, highlighting the importance of a fiber-rich diet and carbohydrate-based fermentation in the healthy gut. Finally, IBD does not always affect identical twins; this observation argues against a strong genetic connection to IBD and supports the hypothesis that the environment and diet are the major triggers of this intestinal condition.

The Role of the Gut Microbiota in Obesity: Mouse Models

Obesity is a significant health risk that contributes to secondary health issues such as high blood pressure, cardiovascular disease, and type 2 diabetes. More than 600 million adults and 100 million children worldwide are obese (defined as a body mass index of >30), and because of this, several studies have focused on possible correlations between the gut microbiome and obesity.

Figure 24.24 Reduced functional capacity of the gut microbiome of patients with inflammatory bowel disease. Metagenomic analysis of human gut microbiota in healthy subjects and patients with inflammatory bowel disease (IBD) revealed a tendency toward fewer nonredundant bacterial genes in patients with IBD.

Initial evidence linking the gut microbiota to host fat accumulation in humans came from studies using germ-free (microbe-free) mice. In these experiments, normal mice had 40% more total body fat than those raised under germ-free conditions, although both mouse populations were fed the same amount and type of food. After germ-free mice were inoculated with fecal material from a normal mouse (a fecal transplant, see later), they developed a gut microbiota and their total body fat increased, although there had been no changes in food intake or energy expenditure.

Experimental colonization of germ-free mice with individual microbial species or microbial communities have demonstrated that colonization triggers the expression of *host* genes for glucose uptake and lipid absorption and transport in the ileum. This indicates that there is likely a link between gut microbial composition and the ability of the host to harvest energy from its diet, ultimately contributing to obesity. This has been demonstrated in experiments with mice. Mice that are genetically obese have microbial gut communities that differ from those of normal mice, with 50% fewer *Bacteroidetes*, a proportional increase in *Firmicutes*, and a greater number of methanogenic *Archaea*. It has been hypothesized that methanogens increase the efficiency of microbial conversion of fermentable substrates to volatile fatty acids (VFAs) by consuming molecular hydrogen (H₂), as also occurs in the rumen (◀ Section 23.16); this makes more VFAs available for absorption by the mouse. In the non-obese mouse, by contrast, fewer H₂-consuming methanogens are present, and the buildup of H₂ functions as a partial inhibitor of microbial fermentation. This favors growth of *Bacteroidetes* species, making fewer VFAs from *Firmicutes* fermentation available for the mouse (Figure 24.25a). What triggers this difference in the methanogen content of lean versus obese mice is not well understood. However, a similar scenario but involving different microbes also appears to be a factor in human obesity (see next subsection).

The importance of the gut community to a predisposition to obesity in mice has also been demonstrated by *fecal transplant studies*, transplanting a small sample of the gut contents from a set of paired

Figure 24.25 Fermentation in the colon of lean and obese mice and transfer of an obese condition by fecal transplant. (a) The greater abundance of methanogens in the gut of obese mice is thought to promote fermentation by consuming H_2 . (b) Transplanting fecal material from the gut contents of a paired identical human twin study group (one twin was obese and the other lean) to germ-free mice showed that the obese twin microbiota made the mouse obese. Conversely, transfer of gut contents from the lean twin did not contribute to an obese phenotype. Part b adapted from Ridaura, V.K., et al. 2013. *Science* 341 doi:10.1126/science.1241214.

human twins (one obese and one lean) into germ-free mice (see Section 24.11 for more coverage of fecal transplants). Although the recipient mice were fed identical high-fiber diets, the mice receiving fecal contents from the obese twin gained significantly more weight than the mice receiving fecal contents from the lean twin (Figure 24.25b). This is direct evidence that a lean or obese body type can be altered by changes in the gut microbiota, even when the microbiota originates from a different species. Put another way, specific but widely distributed gut microbes exist that can control an animal's metabolism to yield a lean or obese body type.

The Gut Microbiota and Human Obesity

Animal model inferences have been more difficult to demonstrate with human subjects, since strict control of diet and host genotype is not feasible and gut microbiota manipulation is more difficult to achieve. Although studies of humans could not confirm the *Bacteroidetes*–*Firmicutes* relationship established in mice, they have shown that obese humans are more likely to harbor species of *Prevotella* and methanogenic *Archaea* than are lean humans, suggesting that a version of the mouse model (Figure 24.25a) is likely

applicable to humans. In humans, the methanogens are proposed to remove H_2 produced by *Prevotella*, facilitating fermentation by *Prevotella* and increasing nutrients to the host. This model is also supported by the study of germ-free mice colonized with *Bacteroides thetaiotaomicron* (having a metabolism similar to *Prevotella*) and the methanogen *Methanobrevibacter smithii*. Relative to controls containing just one of these species, co-colonized mice have a higher number of total gut bacteria, higher acetate levels in the intestinal lumen and blood, and greater body fat.

This relatively simple explanation for the cause of obesity is insufficient to fully explain microbial contributions to obesity. For example, the gut microbiota in lean mice produce greater amounts of the fatty acids propionate and butyrate and actually digest *more* of the plant fiber than do the microbiota of obese mice. Similarly, although a fiber-rich diet increases the amount of material available for fermentation in the human large intestine, such a diet also reduces the risk of obesity. As we now know, this may be an attribute of healthy gut homeostasis (Figure 24.23) where binding of SCFAs to specific intestinal cell surface receptors elevates production of hormones affecting energy recovery and sensations of hunger. Similarly,

obesity in humans is also associated with a variety of metabolic complications, including low-grade inflammation exacerbated by reduced production of SCFAs from a diet low in fiber. These factors tend to complicate the simple microbiota models of obesity proposed to date.

An influence of host physiology on the gut community is also suggested by changes during pregnancy in humans. The period between the first and third trimesters of pregnancy is associated with a decrease in gut microbial diversity and enrichment in the gut community of species of *Proteobacteria* and *Actinobacteria*. These changes are associated with the increased body fat and insulin insensitivity that develop later in gestation. A simple interpretation of these findings is that a pregnant woman's body in some way manipulates her gut microbiome as part of its preparations for a greater demand on stored energy reserves. If true, this once again underscores the complex interplay between the gut microbiota and multiple host variables (genetic, physiological, behavioral, and environmental) that may be contributing factors in the development of human obesity and associated metabolic disorders.

Check Your Understanding

- What is dysbiosis? How might this condition lead to inflammatory bowel disease?
- How are higher numbers of gut *Prevotella* species linked to obesity in humans?
- Why are the gut microbiota results obtained in mice more difficult to confirm through human studies?

24.10 Syndromes Linked to the Oral, Skin, and Vaginal Microbiota

Imbalances in the normal microbiota have been linked to human health issues other than those affecting the gut. These include in particular diseases of the oral cavity, skin, and vagina, and we consider some of these important disease centers here.

Dental Caries and Periodontitis

Dental caries and periodontal diseases are among the most common chronic human maladies. We consider dental caries in Chapter 25, where we examine how bacteria attach to solid surfaces. The mechanisms by which oral bacteria stick to the teeth and gums has been used as a major model system for bacterial attachment to solid surfaces. The attached cells eventually form a diverse microbial community in dental plaque and this leads to dental disease from the generation of lactic acid by fermentation (► Section 25.2 and Figures 25.7 and 25.8). Although *Streptococcus mutans* is a major contributor to dental caries, colonization of tooth surfaces (Figure 24.26) with organisms other than *S. mutans* can also lead to caries. In the absence of *S. mutans*, other acidogenic and acid-tolerant species can initiate caries.

Species of the bacterial genera *Streptococcus*, *Granulicatella*, and *Actinomyces* are typically elevated in children who develop severe early dental caries, whereas caries-free children have a higher relative abundance of *Aestuariimicrobium*. In older children, caries is associated with decreasing bacterial diversity and increasing prevalence of *Porphyromonas* and *Prevotella* species. Similarly, dental plaque is

more microbially complex in healthy subjects than in those with caries. Chronic periodontitis (inflammation and loss of tissue and bone that supports the teeth) is also associated with decreased microbial diversity, although no single bacterial phylotype seems to be directly associated with disease.

Collectively, these observations suggest that no single pathogen leads to the formation of dental caries or periodontal disease, but rather that community-wide changes in microbial composition trigger the diseases. Periodontal disease is particularly serious because it is thought to contribute to several debilitating systemic conditions, including cardiovascular disease, diabetes, pneumonia, and arthritis. Although the etiology of these systemic pathologies is unclear, they appear to be associated at least in part with dysbiosis of the oral cavity similar to that observed in dysbiosis of the gut microbiota in inflammatory bowel disease (Section 24.9).

Acne Vulgaris

The interrelationship of species of the bacterial genus *Propionibacterium* with the innate and adaptive arms of immunity (Chapters 26

Figure 24.26 Colonization of tooth surfaces. (a) The colonies are growing on a model tooth surface inserted into the mouth for 6 h. (b) Higher magnification of the preparation in part a. Note the diverse morphology of the organisms present and the slime layer (arrows) holding the organisms together.

and 27, respectively) has been examined extensively because of the association of this bacterium with *acne vulgaris*, usually just called *acne*, a cutaneous inflammatory disease of the skin that affects more than 85% of adolescents worldwide. However, the suspected causative agent of acne, *P. acnes*, is also a member—and a dominant member—of the normal cutaneous microbiota (Figures 24.2 and 24.15–24.17) and thus is also present in individuals without inflammatory disease.

Although *Propionibacterium* species have the capacity to elicit an inflammatory response, this alone is insufficient to demonstrate a causal association with disease. A better understanding of the cause(s) of acne will likely emerge from a better understanding of variation among strains of *P. acnes*. Notably, experiments using metagenomic and multilocus sequence analysis (◀ Section 13.12) suggest that a specific strain of *P. acnes* in susceptible individuals may trigger the acne condition, whereas a much greater diversity of strains is observed among individuals having good skin health. Because of the scarcity of nutrients available for the skin microbiota, even minor differences in nutritional requirements between strains may favor the development of one or another *P. acnes* strain. If true, this might lead to therapies for acne using probiotics or prebiotics (see Section 24.12) that foster the growth of harmless strains or the growth of other species that displace *P. acnes* through competition for space and nutrients. For example, a lotion could be applied to the skin that contains a nonpathogenic strain or a nutrient selective for protective strains as a means to prevent or limit colonization by pathogenic strains.

Vaginal Conditions

Dysbiosis of the normal vaginal microbiota (Section 24.4 and Figure 24.14) is associated with either an inflammatory infection (*vaginitis*) or a less severe clinical form (*vaginosis*) that may be asymptomatic or associated with malodor and discharges. Common types of vaginitis result from the overgrowth of species of the yeast *Candida* (candidiasis) or from infection by the sexually transmitted protozoan *Trichomonas vaginalis*, both discussed in Chapter 34. Diagnosis of the less highly inflammatory vaginosis in a clinical research lab is commonly based on a microscopic scoring of a Gram-stained vaginal smear. However, culture-independent molecular methods (Chapter 19) are increasingly being employed to more precisely define vaginal communities associated with health, disease, and predisposition to disease, including neonatal infections, miscarriage, pre-term birth, and increased susceptibility to HIV and sexually transmitted infections.

Longitudinal studies of individual women over multiple months have revealed that the vaginal microbial communities of some women are highly dynamic, changing in composition over relatively short time periods, whereas the communities of others are relatively stable (Figure 24.27). Most vaginal microbial communities appear to be stable, displaying *resilience* (the capacity to return to the pre-disturbance community structure following disruption, such as menstruation) or *resistance* (the capacity to resist community disruption in response to disturbance). For example, a low pH-tolerant, *Lactobacillus crispatus*-dominated vaginal community is relatively stable (Figure 24.27), showing either resilience (subject 1) or resistance (subject 2). By contrast, other vaginal communities are

Figure 24.27 Resilience of the normal vaginal microbiota in two subjects. Both vaginal communities were dominated by *Lactobacillus crispatus* and demonstrated resilience to perturbation, most notably the disruption associated with menstruation (indicated by horizontal red bars) in subject 1.

more prone to converting to a vaginosis form. For example, the healthy *L. crispatus*-dominated community can convert to a healthy *L. iners*-dominated community before returning to *L. crispatus* (Figure 24.27). However, although both the *L. crispatus* and *L. iners* communities are associated with vaginal health, an *L. iners*-dominated community is more likely to transition to vaginosis. Vaginal bacterial diversity also waxes and wanes over shorter time periods, such as a woman's menstrual cycle. Higher bacterial diversity is observed during days of menstruation than in intervening days, with diversity following a cycle inversely related to that of the estrogen hormone estradiol.

As for most ongoing human microbiome research, molecular microbial community analyses of the vagina have revealed connections between the microbial diversity of the vagina, vaginal health, and the susceptibility to vaginal diseases. However, we do not yet fully understand how the vaginal community is established and maintained or how vaginal dysbiosis develops and resolves. Nevertheless, if some community types are associated with clinical symptoms or are associated with higher risk for vaginal disorders, then early intervention may be important to maintaining women's health and the health of a mother and baby in particular.

Check Your Understanding

- What observations indicate that dental caries are not due solely to *Streptococcus mutans*?
- Why might it be possible to have a high abundance of *Propionibacterium acnes* without developing acne vulgaris?
- What are some clinical advantages of a community-structure-based evaluation of vaginal health?

V • Modulation of the Human Microbiome

Gut dysbiosis can be resolved by introducing microbes from a healthy gut by fecal transplant. Selective modulation of the gut community can be accomplished by the use of probiotics and prebiotics. Early intervention with such therapies can reduce the incidence of serious intestinal disease in infants.

One important basic-science goal of human microbiome studies is to understand how the microbial composition and activity of human-associated microbes promotes health or predisposes the body to a variety of health disorders. Here we look at how the introduction of specific microbes or even transplants of the entire gut community can be used to promote health.

24.11 Antibiotics and the Human Microbiome

Antibiotics are naturally produced antimicrobial substances whose efficacy varies against different bacteria (Chapter 28). However, when an antibiotic is taken orally it kills or inhibits to at least some extent the normal microbiota as well as the targeted pathogen(s). Antibiotic treatment can lead to a significant loss of the normal gut microbiota (Section 24.2). When antibiotic therapy ends, the normal intestinal microbiota is usually, but not always, reestablished spontaneously in adults.

Use of antibiotics during the first few months of life is a particular problem for the developing normal microbiota. This disruption can affect normal development of the immune system and predispose the infant to later autoimmune disorders, such as IBD and allergies (Section 24.9). Research has also shown that early disruption of the gut microbiota influences host energy metabolism. For example, antibiotic exposure during the first 6 months of life is associated with increased weight gain in infants between 10 and 38 months of age compared to those not receiving antibiotics. With growing concerns about the frequency of childhood obesity leading to adult obesity along with the growing number of childhood autoimmune disorders, it is clearly important to avoid, if possible, disruption of the normal development of the human gut microbiota early in life.

Clostridioides difficile Infections

Sometimes antibiotic-resistant opportunistic pathogens become established in young children or the elderly following antibiotic treatment that disrupts the normal microbiota. A particularly problematic complication of antibiotic therapy is infection with toxigenic *Clostridioides difficile* (► Section 30.7) and the inability to resolve infections with repeated follow-on administrations of antibiotics (Figure 24.28). There is a strong association between antimicrobial therapy and the subsequent development of *C. difficile* infection, and the risk of infection is greater if *C. difficile* is resistant to the antimicrobial agents used in therapy.

In those infected with *C. difficile*, symptoms vary from a mild diarrhea to severe abdominal pain and fever. The most severe complications are inflammatory lesions and bowel perforation; as a result of these, septic shock (► Section 25.2) and death are possible. In the past, if intravenous fluids and antibiotics did not resolve the infection, then surgical removal of the colon was a last-resort lifesaving measure.

Figure 24.28 Antibiotic treatment increases the risk of *Clostridioides difficile* infection. During antibiotic therapy the displacement of sensitive gut populations results in a significant loss of community diversity, allowing antibiotic-resistant populations such as toxigenic *C. difficile* to increase in abundance. When antibiotic therapy ends, *C. difficile* may be displaced (solid green line) by reestablishment of a normal gut microbiota, or alternatively it may persist (dotted line), causing intestinal disease.

However, the prognosis for recovery from a *C. difficile* infection today has been dramatically improved by a novel nondrug and nonsurgical therapy: the infusion of fecal material from the gut contents of a healthy donor into the gut of a *C. difficile*-infected patient—more commonly called a *fecal transplant*. In most cases such treatment has been shown to restore a healthy colon in patients suffering recurring *C. difficile* infections, and we examine this procedure now.

Fecal Transplants

The goal of a **fecal transplant** is to reintroduce normal microbiota into the gut of someone with an intestinal disease of bacterial origin and have the transplanted microbial community become established and exclude the disease-causing organisms. Although it has taken the medical community some time to adopt this therapy, the dramatic improvement in the rate of resolution from *C. difficile* infection by fecal transplant from a healthy donor has prompted widespread adoption of this procedure.

As we have seen, once established, *C. difficile* is a particularly difficult pathogen to eradicate (Figure 24.28). However, the percentage of otherwise nonresponsive patients cured of *C. difficile* infection without relapse is nearly 90% with fecal transplant therapy versus only about 25% with standard antibiotic treatment. It has also been shown that fecal transplants can alleviate some forms of metabolic syndrome, a condition that is characterized by elevated blood pressure and glucose levels, excess belly fat, and abnormal cholesterol levels and that is a frequent precursor of type 2 (insulin-nonresponsive) diabetes. Metabolic syndrome patients receiving a fecal transplant from a lean donor had significantly increased insulin sensitivity, and also showed increased fecal levels of butyrate, greater overall gut microbial diversity, and increased abundance of the gut bacterium *Roseburia intestinalis*, thought to be a beneficial microbe because of its butyrate production (Figure 24.23).

Fecal transplants require that the donor be healthy and free of infection. And, because feces are considered a body fluid, screening and testing of the donor is essential. Potential donors must complete a screening questionnaire similar to that required for donating blood, and any prospective donors who have risk factors for HIV (AIDS) or hepatitis infections or any history of gastrointestinal

disease, autoimmune disease, or cancer are screened out. Prospective fecal donors must also undergo blood tests for a suite of pathogens, and their feces are tested for fecal bacterial pathogens and parasites. If everything checks out, samples of their feces are frozen in small vials and then thawed and used when needed. Fecal transplant recipients typically receive the transplant via a saline solution during colonoscopy to ensure that the transplanted feces actually reach the upper colon and that the colon has previously been cleansed to remove as much of the previous microbial community as possible.

Although a fecal transplant may seem somewhat crude and an essentially uncontrolled or nonprecise therapy, studies are accumulating that show that the appropriate manipulation of the gut microbiota can have significant health benefits and that gut microbiota transplants can be maintained for long periods. More generally, the success of fecal transplants has shown that manipulation of the human microbiome for improved health is feasible and that with greater understanding of these complex communities, more targeted intervention may be possible, as we consider in the next section.

Check Your Understanding

- Why do healthy adults usually not contract *Clostridioides difficile* infections?
- Why is it unsafe for a fecal transplant recipient to receive feces from an unscreened donor?

24.12 Probiotics, Prebiotics, and Synbiotics

We close this chapter with a brief discussion of how ingestion of living microbial cultures (*probiotics*), particular nutrients typically derived from plants (*prebiotics*), or a combination of probiotic and prebiotic (called *synbiotic*) supplements could be used to treat disease and promote health by modulating the gut microbial community.

Probiotics

The United Nations Food and Agriculture Organization and the World Health Organization define a **probiotic** as a “live microorganism which, when administered in adequate amounts, confers a health benefit on the host.” Species of *Bifidobacterium* and *Lactobacillus* bacteria are the most commonly discussed probiotics. They are usually delivered to the gastrointestinal system by ingestion of a fermented milk product, such as yogurt (Figure 24.29), with the hope of suppressing gut or urogenital disturbances.

Most physicians and scientists agree that ingestion of probiotic foodstuffs probably has limited therapeutic value. Nevertheless, human microbiome research has spurred a renaissance in probiotics research and investment, especially for the development of effective and more targeted probiotics. The remarkable success of fecal transplants (Section 24.11) points to the therapeutic potential of modification of the gut microbiome. However, although fecal transplants have proven very effective, there is minimal understanding of the mechanisms behind their successes and also why they do not work in a limited number of cases.

Molecular analyses of *Clostridioides difficile* infections have highlighted the importance of a mechanistic understanding for the development of effective probiotic therapies. Resistance to *C. difficile* infection following antibiotic therapy (Figure 24.28) in both mice and humans is correlated with the presence of a *Clostridium* species,

Deborah O. Jung and John Martinko

Figure 24.29 Examples of some probiotic foods and supplements widely available worldwide. Some probiotic products also contain prebiotics (specific polysaccharides obtained from various plants and other sources).

C. scindens. Administration of this species to mice infected with *C. difficile* has been shown to be an effective probiotic therapy; suppression has been linked to the ability of *C. scindens* to convert cholic acid (found in bile) into deoxycholic acid, a growth inhibitor of *C. difficile*. In similar studies, recovery from diarrhea caused by *Vibrio cholerae* (cholera, ► Section 33.3) has been associated with an increased abundance of the bacterium *Ruminococcus obeum*. Mouse studies demonstrated that production of a quorum-sensing autoinducer (AI-2) (◄ Section 7.7) by *Ruminococcus* suppressed expression of *V. cholerae* colonization factors and effectively prevented the cholera bacterium from establishing an infection.

The promise of effective probiotic therapies suggested from mouse studies have been supported in several human studies. For example, the fortuitous ingestion of a *Bacillus* strain present in a rural Thai environment was shown to prevent colonization by pathogenic *Staphylococcus aureus*. Similar to the mechanism of action observed in *R. obeum*, the *Bacillus* prevents colonization by interfering with the *S. aureus* quorum-sensing signaling system, ultimately preventing transcription of genes encoding virulence (Figure 24.30). This particular *Bacillus* strain could thus be marketed as an effective probiotic to eliminate intestinal as well as nasal *S. aureus* colonization. This is important because treatment of *S. aureus* infections has become increasingly difficult due to the prevalence of multi-antibiotic-resistant strains, such as methicillin-resistant *S. aureus* (MRSA; ► Section 31.9). Thus, an effective probiotic therapy that targets a specific pathogen and avoids the disruptive impact of broad-spectrum antibiotics on the human microbiome (see Section 24.11) would be a powerful addition to clinical medicine.

Probiotics have also been shown effective in reducing the incidence of necrotizing enterocolitis (NEC), a severe inflammatory injury to the intestines of low-birthweight premature infants. NEC affects as many as 10% of premature infants, and about a quarter of those affected will die. Molecular characterization by 16S rRNA gene sequencing (◄ Section 19.6) of the developing gut communities in these infants showed that during the first 60 days of life, species of *Veillonellaceae* (*Negativicutes*) and *Clostridia* increased in infants not developing NEC but were displaced by increasing numbers of *Enterobacteriaceae* species in those developing NEC (Figure 24.31). Thus, NEC is a type of dysbiosis, the disruption of the normal sequence of gut colonization.

Figure 24.30 Probiotic inhibition of *Staphylococcus aureus* intestinal colonization. Some intestinal *Bacillus* species prevent colonization of the opportunistic pathogen *S. aureus* by producing fengycin, an inhibitor of quorum sensing that is structurally similar to the autoinducing peptide (AIP) made by *S. aureus*. Fengycin binding to the ArgC sensor kinase (◀ Figure 7.20) inhibits AIP binding but does not induce the signal transduction required for virulence gene expression and colonization of the gut by *S. aureus*.

The most effective preventive treatment of NEC has been the probiotic feeding of commercially available species of *Bifidobacterium* and *Lactobacillus*; early treatment with these bacteria reduced the risk of death by 25%, likely by competing for space and resources with pathogenic enteric bacteria. From these promising results, current research is focused on identifying the most effective species and strains in hopes of more precisely targeting probiotic treatment of NEC and getting the gut microbiome of premature infants back on a normal track (Section 24.8).

Prebiotics and Synbiotics

Probiotics should not be confused with *prebiotics*. The **prebiotic** approach to developing a healthy normal microbiota promotes the ingestion of certain nutrients as microbial growth stimulants with the idea that they will nurture particular bacterial species already present in the gut and known to be associated with a healthy colon. Prebiotics are typically carbohydrates that are indigestible by the body but are excellent carbon and energy sources for certain fermentative gut bacteria. Fructooligosaccharides, polymers of the sugar fructose present in many vegetables, are thought to stimulate desirable gut microbes, and the complex polysaccharide *inulin* is widely promoted commercially as a major prebiotic.

Figure 24.31 Dysbiosis contributing to necrotizing enterocolitis of premature infants. Inflammation and necrosis of the infant's intestine is associated with an overgrowth of enteric bacteria, displacing protective species such as those of the *Veillonellaceae* and the genus *Clostridium*.

Some probiotic formulations (such as certain yogurts) contain prebiotics as well to supply both beneficial aspects in a single treatment; these combined formulations are called **synbiotics**. The prebiotic in a synbiotic is added to promote the growth and colonization of the probiotic organism. The most dramatic success of synbiotics has been in the treatment of sepsis in young children. Sepsis in newborns, a systemic infection originating from an inflammation of the gut similar to NEC, is a major cause of child illness and death in the developing world, causing over half a million deaths a year. A synbiotic containing *Lactobacillus plantarum* and fructooligosaccharide given orally to newborns for 7 days beginning 2 days after birth reduced the risk of death from sepsis by 40% in a trial in India. This again demonstrates the importance of early intervention in gut colonization for preventing dysbiosis with its complications of possible sepsis and later life health problems.

The remarkable success of these treatment examples offers tremendous hope for future development of effective and inexpensive therapeutic agents for the prevention of disease and improved human health. The most successful advances to date have come from careful scientific studies based on our steadily improving understanding of the developing and mature microbiome and its relationship with its human host.

Check Your Understanding

- What is a probiotic? How does it differ from a prebiotic and a synbiotic?
- Why do you think fecal transplants have stimulated renewed research into the development of probiotic and prebiotic therapies?
- Explain how probiotics based on interference of quorum sensing can suppress infection.

CHAPTER REVIEW

Go to **Mastering Microbiology** for videos, animations, practice tests, and more.

I • Structure and Function of the Healthy Adult Gastrointestinal and Oral Microbiomes

- 24.1** The human body is colonized by a diverse assemblage of microorganisms in numbers that approximately equal the total number of cells in the human body. Different body sites provide distinctive habitats that influence the types of microorganisms inhabiting each site. Collectively, these microbes constitute the human microbiome, now recognized to be intimately associated with human health and disease.

Q Why is understanding the nature of the human microbiome such a complex process?

- 24.2** The human gastrointestinal tract is composed of many segments that differ dramatically in their nutritional and pH characteristics and support quite distinct bacterial populations.

Q How do microbial diversity and abundance vary along the length of the gastrointestinal tract?

- 24.3** Distinctive groups of microorganisms colonize the mucous membranes and hard surfaces of the mouth and are constantly shed in saliva. The different microhabitats of the mouth (hard and soft surfaces, gingival crevice) sustain a high diversity of both aerobic and anaerobic populations.

Q Why does saliva not serve as a good microbial growth medium?

II • Urogenital Tract and Skin Microbiomes and the Human Viral Microbiome

- 24.4** With the exception of the vagina and distal urethra, the male and female urogenital tracts harbor no or few microorganisms. The healthy vaginal microbial community is dominated by *Lactobacillus* species, which suppress the growth of other populations by lowering the vaginal pH to about 5 through fermenting glycogen to lactic acid.

Q How does the composition of different species of *Lactobacillus* in the vaginal community impact predisposition to infection?

- 24.5** The skin is a complex human organ covering about 2 square meters of the body and hosting about 10^{10} microorganisms in the healthy adult. Microbial community composition varies among the diversity of skin sites, generally categorized as moist, dry, or oily. The most common skin microorganisms are bacteria of the phyla *Actinobacteria* and *Firmicutes*.

Q What characteristic of *Propionibacterium* species accounts for their colonization of the sebaceous gland system?

- 24.6** The human virome consists of the vast diversity of animal and bacterial viruses that colonize the body and its

microbiome. The greatest diversity and abundance of viruses is found in the gut, consisting of many novel bacteriophages that infect that complex microbial community. Unlike the environmental virosphere, where phage virions greatly exceed microbial cell numbers, most gut phages are lysogenic and have unknown impact on the gut microbial ecology.

Q What accounts for the low ratio of virions to bacteria in the gut compared to the open environment, such as in the ocean (◀ Section 20.13)?

III • From Birth to Death: Development of the Human Microbiome

- 24.7** Our current understanding of relationships between the human microbiome and health status is derived from complementary studies of select human study groups and experimental manipulation of animal models, in particular the mouse. Human studies are limited by incomplete control of lifestyle and genetic factors influencing the microbiome. Animal studies are limited by differences from humans in microbiology, anatomy, and physiology.

Q What are the major anatomical differences between mouse and human gastrointestinal systems, and how might those differences influence microbial composition?

- 24.8** The newborn gut microbial community evolves into a more complex adultlike community over the first 2–3 years of life. Initial colonization is influenced by vaginal or C-section delivery and by feeding of breast milk or formula. The unique oligosaccharides in human breast milk suppress pathogen colonization and select for beneficial microorganisms such as *Bifidobacterium* species. Changes in the gut microbial community with age have been associated with frailty in the elderly.

Q When a child is transitioned from breast milk to solid food, what are the associated changes in the gut microbial community and what physiological differences do those changes reflect?

IV • Disorders Attributed to the Human Microbiome

- 24.9** The two major disorders associated with changes in the human gut microbial community are inflammatory bowel disease and obesity. Inflammatory bowel disease is associated with dysbiosis, a breakdown in the normal interactions between the human host and its intestinal microbiota reflected by reduced diversity of microbial genes in the diseased state. Obesity is associated with the microbial community composition of the gut, which influences host energy recovery, but obesity is likely not determined by a single contributing microbial or host factor.

Q How are short-chain fatty acids associated with good health as well as with inflammatory bowel disease and obesity?

24.10 Dental caries and periodontitis are diseases of the mouth caused by the combined activities of multiple microbial species, not a single pathogen. Strain variation among *Propionibacterium* species is associated with ability to cause acne, a common cutaneous inflammatory disease of adolescents. The vaginal community is dominated by *Lactobacillus* species that limit colonization by other organisms through lowering pH by production of lactic acid. Although generally very resilient to perturbation, the vaginal community transitions to a more diverse community during menstruation and during incidents of vaginitis or vaginosis.

Q Why might a therapy based on colonization of the skin by selected *Propionibacterium* strains be effective in preventing the development of acne?

V • Modulation of the Human Microbiome

24.11 Antibiotic therapy may predispose an individual to infection by *Clostridioides difficile*, a toxigenic bacterium that causes severe intestinal disease, because oral antibiotics reduce competition from the normal microbiota of the gut.

Infections that cannot be resolved by standard or repeated antibiotic therapy have been shown to respond to fecal transplants, which introduce fecal material from a healthy donor into the gut of the infected individual.

Q Why has the success of fecal transplants in treating *C. difficile* infection encouraged the development of therapies based on microbial ecology for other disorders associated with the human microbiome?

24.12 Probiotics are live microorganisms that, when administered in adequate amounts, confer a health benefit on the host. New understanding of the mechanisms by which organisms such as *Clostridium scindens* and *Bacillus* species suppress pathogen colonization show that targeted probiotics can likely be developed to prevent or treat certain diseases. Prebiotics are nutritional supplements thought to promote the growth of beneficial gut microbes. Synbiotics combine a prebiotic with a probiotic to enhance the efficacy of the probiotic.

Q What is the mechanism by which certain *Bacillus* species suppress colonization by pathogenic *S. aureus*?

APPLICATION QUESTION

1. You are told that you must be placed on a high dose of a broad-spectrum antibiotic to treat a serious infection. You are concerned that this therapy will seriously disrupt your intestinal microbiota, possibly leading to intestinal disease such as that caused by *Clostridioides difficile*. In advance of the treatment,

what might you do to ensure that your normal intestinal microbiota is restored after extended antibiotic therapy? Discuss two ways this restoration could be accomplished, one that would return your exact microbiota and one that would return some representative species.

CHAPTER GLOSSARY

Dysbiosis an alteration or imbalance of an individual's microbiome relative to the normal, healthy state, primarily observed in the microbiota of the digestive tract or the skin

Fecal transplant the transfer of microbiota from the colon of one individual into the colon of another

Host an organism that can harbor pathogenic or beneficial (micro)organisms

Human microbiome the total microbial content in and on the human body

Lower respiratory tract the trachea, bronchi, and lungs

Microbiome a functional collection of different microbes in an environmental system such as the human body

Microbiota the types of organisms present in an environmental habitat, such as the

human skin or the human gastrointestinal tract

Mucin a secretion from specialized epithelial cells containing water-soluble glycoproteins and proteins, forming the mucus that retains moisture and impedes microbial invasion on mucosal surfaces

Normal microbiota microorganisms that are usually found associated with healthy body tissue

Prebiotic food additive that promotes the growth and activity of beneficial microorganisms, usually in the gastrointestinal tract

Probiotic a live microorganism that, when administered in adequate amounts, confers a health benefit on the host

Short-chain fatty acids (SCFAs) also called volatile fatty acids or VFAs, these are

the major fatty acids (acetate, propionate, and butyrate) produced during fermentation in the large intestine of monogastric animals and the rumen or cecum of herbivores

Synbiotic a mixture of probiotic and prebiotic that beneficially affects the host by altering the microbiome

Upper respiratory tract the sinuses, nasal and oral cavities, and structures of the throat—the pharynx, tonsils, and larynx

Killing Pathogens on Contact

The adherence of pathogenic bacteria to surfaces plays a crucial role in their ability to colonize areas of the body and cause disease. In addition to natural tissue surfaces in the body, such as tooth enamel and mucous membranes, pathogens can also adhere to artificial surfaces associated with implanted medical devices, including catheters, prosthetic heart valves, and artificial joints. The adherence of bacteria to these sites can lead to the formation of biofilms, which are notoriously difficult to treat using antibiotics.

Because of the tendency of pathogenic bacteria to colonize artificial surfaces in the body, prosthetic joint infections (PJIs) are a constant threat in orthopedic medicine. Considering the ineffectiveness of antibiotics in treating these infections, successful treatment of PJIs often requires physical removal of the colonized biofilm from the prosthesis and surrounding tissues in a surgical procedure called *debridement*. To avoid the complications of treating infection, can we find ways to prevent the formation of biofilms that lead to PJIs in the first place?

Taking a lesson from nature itself, researchers are turning to the field of *biomimetics* to address these issues. Several

animal and plant tissue surfaces exhibit antibacterial properties, including shark skin, insect wings, and lotus leaves. Such natural surfaces are composed of nanostructures that kill bacteria on contact, likely by disrupting the integrity of their cytoplasmic membranes. Borrowing this concept, antibacterial nanofabrication methods have centered on titanium dioxide (TiO_2) as a potential substrate to mimic natural contact killing. Although TiO_2 has shown limited potential for killing gram-positive cocci, such as *Staphylococcus aureus* (bottom photo), it has shown considerable promise in destroying gram-negative bacteria on contact, including *Escherichia coli*, in which the spiky nanostructures cause indentation and eventual puncture of the cells (arrow, top photo).

If artificial joints and other medical implants can be manufactured with surfaces having antibacterial nanostructures, PJIs and other biofilm-associated infections may become much easier to prevent and control—no antibiotics necessary.

I • Human–Pathogen Interactions

To induce pathogenesis and begin to parasitize the host, pathogenic microbes must first adhere to host tissues and overcome immune defenses that seek to inhibit microbial colonization and invasion.

Humans are exposed to microorganisms of all sorts in their environment. Whether one is walking outdoors, sitting indoors, or participating in any type of physical activity, environmental microbes and humans interact. The human body is also a natural home to enormous numbers of microorganisms, as we saw in Chapter 24. Most of these are harmless, and in fact essential, with only a small percentage capable of causing disease. However, those that do, along with pathogens that are not part of the normal human microbiota, possess specific traits that underlie their pathogenic lifestyles. A major focus of this chapter will be a consideration of these specific traits and how they induce the diseased state.

25.1 Microbial Adherence

In the world of infectious diseases, the term **infection** is used to imply the growth of microorganisms on or in the host, whereas the term **disease** is reserved for actual tissue damage or injury that impairs host function. If a **pathogen** gains access to the specific tissues it infects, disease will occur only if it first adheres to those tissues, multiplies to yield many cells or viral particles, and then proceeds to damage tissues (or the entire organism) by the release of toxic or invasive substances (**Figure 25.1**). Adherence is the first step, and although adherence is *required* to initiate disease, it is not *sufficient* to initiate disease because the host has many innate defenses that can thwart infection; we consider these in Chapter 26.

Adherence Molecules

Pathogens typically adhere to epithelial cells through specific interactions between molecules on the pathogen and molecules on the host tissues. In addition, pathogens may adhere to each other, forming biofilms (◀ Sections 4.9 and 20.4), with the biofilm itself adhering to specific tissues. In medical microbiology, **adherence** is the enhanced ability of a microorganism to attach to a cell or a surface. Pathogens gain access to host tissues by way of a *portal of entry* of one

Figure 25.2 Bacterial adherence. A bacterial pathogen attaches specifically to host tissues by way of complementary receptors on the bacterial and host surfaces. (a) Cryogenic transmission electron micrograph of the gram-positive bacterium *Staphylococcus aureus* adhering to an extracellular matrix of fibrinogen, which the cells convert to a fibrin clot as a defense against host immune responses (see also Figure 25.12b). The *S. aureus* cells are about 0.75 μm in diameter. (b) Expanded diagram of *S. aureus* binding fibrinogen using the N2 and N3 domains of its SdrG adhesin protein.

sort or another. These include mucous membranes, the skin surface, or under mucous membranes or the skin during penetration of these sites from puncture wounds, insect bites, cuts, or other abrasions. The portal of entry may be critical for the establishment of an infection because a pathogen that gains access to incompatible tissues is typically ineffective. For example, if cells of the bacterium *Streptococcus pneumoniae* are swallowed, they will be killed by the strong acidity of the stomach, whereas if the same cells reach the respiratory tract, they could trigger a fatal case of pneumonia.

Receptor molecules coating the surfaces of both the pathogen and cells of its host are often critical for adhering the pathogen to host tissues. Specific receptors can be important for the binding of any type of pathogenic microbe, including bacteria, viruses, and parasites (**Figure 25.2**). Receptors on pathogens have evolved to bind specifically to complementary molecules in the host, and the complementary nature of the receptors on pathogen and host cells alerts the pathogen that it has arrived on a suitable infection site. Receptors on the pathogen surface are called **adhesins** and are composed of glycoprotein or lipoprotein covalently bound to the outer

layer of the cell (Figure 25.2b). In addition to extracellular matrices, such as the fibrinogen shown in Figure 25.2, host receptors for bacterial adhesins include cell surface glycoproteins or complex membrane lipids, such as gangliosides or globosides (both are sphingolipids containing sugars and other molecules).

Adherence Structures: Capsules, Fimbriae, Pili, and Flagella

Some adhesins form part of an outer cell surface structure that may or may not be covalently linked to components of the cell wall. For example, some notable pathogenic bacteria form a **capsule**. In *Bacillus anthracis* (the bacterium that causes anthrax), the capsule is composed of polypeptide containing only the amino acid D-glutamate. The capsule of *B. anthracis* can be seen in cells by light microscopy, and the encapsulated cells form smooth, slimy colonies when grown on agar plates (Figure 25.3). The electron microscope can also clearly reveal bacterial capsules (Figure 25.3c). The capsule surface contains specific receptors that facilitate adherence to host tissues, but the inherently sticky nature of the capsule itself also assists in the overall attachment process. Although capsules are important for adherence of some pathogens to host tissues, many important pathogens, such as *Vibrio cholerae*, the causative agent of the disease cholera, lack them.

Besides adherence, capsules are important for protecting pathogenic bacteria from host defenses. For example, the only known virulence factor for *Streptococcus pneumoniae* (bacterial pneumonia) is its polysaccharide capsule (Figure 25.4). Encapsulated strains of *S. pneumoniae* grow abundantly in the lungs where they initiate host responses that interfere with lung function, cause extensive host damage, and can cause death (► Section 31.2). By contrast, nonencapsulated strains of *S. pneumoniae* are quickly and efficiently ingested and destroyed by phagocytes, white blood cells that ingest and kill bacteria by a process called *phagocytosis* (► Sections 26.5–26.7).

Figure 25.4 Capsules and colonies of *Streptococcus pneumoniae*. (a)

Gram stain of *S. pneumoniae* cells; capsules are not visible. (b) *S. pneumoniae* treated with anticapsular antibodies (Quellung reaction) that make the capsule visible. (c) Colonies of encapsulated *S. pneumoniae* cells grown on blood agar show a mucoid morphology with a sunken center. The colonies are about 2–3 mm in diameter and a single cell of *S. pneumoniae* is about 0.8 μm in diameter.

Many pathogens selectively adhere to particular types of cells through cell surface structures other than adhesins, capsules, or slime layers. For example, *Neisseria gonorrhoeae*, the pathogen that causes the sexually transmitted disease gonorrhea (► Section 31.13), adheres specifically to mucosal epithelial cells in the genitourinary tract, eye, rectum, and throat; by contrast, other tissues are not infected. *N. gonorrhoeae* has a cell surface protein called Opa (opacity associated protein) that binds specifically to a host protein found only on the surface of epithelial cells of these body regions, allowing adherence of the pathogen to host cells. Likewise, influenza virus targets upper respiratory tract mucosal cells and attaches specifically to these and later to lung epithelial cells by way of the protein hemagglutinin present on the virus surface (◄ Section 11.9 and ► Section 31.8).

Fimbriae and pili are bacterial cell surface protein structures (◄ Section 2.6) that function in attachment (Figure 25.5). For instance, along with Opa, the pili of *Neisseria gonorrhoeae* play a key role in attachment to urogenital epithelia, and fimbriated strains of *Escherichia coli* are more frequent causes of urinary tract infections than strains lacking fimbriae. Among the best-characterized fimbriae are the *type I fimbriae* of enteric bacteria (*Escherichia*, *Klebsiella*, *Salmonella*, and *Shigella*), which are uniformly distributed on the surface of cells (Figure 25.5). Pili are typically longer and fewer in number than fimbriae, and in addition to attachment, some pili function in the bacterial genetic transfer process of conjugation (◄ Section 9.8). Both pili and fimbriae function by specifically binding to host cell surface glycoproteins, thereby initiating adherence. Flagella may also facilitate adherence of bacterial cells to host cells (Figure 25.5), although their role is thought to be less important than that of fimbriae and pili.

Check Your Understanding

- What event is required but not sufficient to cause an infectious disease?
- Describe the molecules or structures that facilitate pathogen adherence to host tissues.

Figure 25.5 Fimbriae. Computer-generated image of a scanning electron micrograph of cells of *Salmonella enterica* (*typhi*) showing the numerous thin fimbriae and the much thicker peritrichously arranged flagella. A single cell is about 1 μm in diameter.

25.2 Colonization and Invasion

If a single pathogenic virus or cell attaches to its specific host tissue, it alone is insufficient to cause disease; the pathogen must establish residence there and multiply. **Colonization**, the growth of a microorganism after it has gained access to host tissues, begins at birth as a newborn child is naturally exposed to a suite of harmless (and in many cases necessary) bacteria and viruses that will be the infant's initial normal microbiota (Chapter 24).

The human body is rich in organic nutrients and provides conditions of controlled pH, osmotic pressure, and temperature that are favorable for the growth of microorganisms. However, each body region, such as the skin, respiratory, gastrointestinal, and genitourinary tracts, differs chemically and physically from others, and thus provides a selective environment for the growth of certain microbes and not others. The result is that pathogens show rather rigid tissue specificities (► Table 26.1), and this reality is often helpful in the diagnosis of microbial infections.

Colonization typically begins at sites in the **mucous membranes** (Figure 25.6). Mucous membranes are composed of *epithelial cells*, tightly packed cells that interface with the external environment. They are found throughout the body, lining the urogenital, respiratory, and gastrointestinal tracts. The epithelial cells in mucous membranes secrete **mucus**, a thick liquid secretion that contains water-soluble proteins and glycoproteins. Mucus retains moisture and naturally inhibits microbial attachment because most microbes are swept away by physical processes, such as swallowing or sneezing. Nevertheless, some microbes—both pathogens and nonpathogens—adhere to the epithelial surface and colonize. If these attached microbes are pathogens, it sets the stage for infection, invasion, and disease (Figure 25.1). Nonpathogenic microbes that penetrate mucous membranes include large numbers—potentially many billions—of innocuous bacteriophages that contribute to what has

been called the “intrabody phageome.” Although poorly understood, the human phageome may play a role in modulating inflammation and other immune responses, which may have implications in controlling autoimmune diseases such as type 1 diabetes and Crohn's disease (► Section 28.1).

Growth of the Microbial Community: An Example from Human Dental Caries

Infection requires growth of the pathogen after it has attached to and colonized a surface (Figures 25.1 and 25.6), and the actual disease process may not be the result of a single type of microbe but of a community of interacting microorganisms. An example of this is found in the oral microbial disease **dental caries** (tooth decay), where attachment and infection have been well studied as models of these key events in the disease process.

Even on a freshly cleaned tooth surface, acidic glycoproteins from the saliva form a thin organic film several micrometers thick; this film provides an attachment site for bacterial cells, and oral streptococci quickly colonize it. These include in particular the two *Streptococcus* species most often implicated in tooth decay: *S. sobrinus* and *S. mutans*. Both of these organisms produce a capsule (Section 25.1). The *S. sobrinus* capsule contains adhesins specific for host salivary glycoproteins (Figure 25.7a, b), whereas *S. mutans* resides in crevices and small fissures where it relies on dextran—a strongly adhesive exopolysaccharide—that it produces to secure cells to the tooth and gum surface (Figure 25.7c, d). Both *S. sobrinus* and *S. mutans* are lactic acid bacteria (◄ Section 16.6) that ferment glucose to lactic acid, the agent that destroys tooth enamel. However, the trigger for decay activities is *sucrose* (table sugar), since it is sucrose that allows these species to produce the dextran exopolysaccharide and capsules necessary for attachment and colonization.

Extensive bacterial growth of these oral streptococci results in a thick biofilm called **dental plaque** (Figure 25.7). Using phylogenetic probes, it has been possible to more thoroughly explore the microbial diversity of dental plaque, and it is clear that the two *Streptococcus* species are not the entire story. Many other gram-positive and gram-negative *Bacteria* are present in plaque, including species of *Corynebacterium*, *Porphyromonas*, *Leptotrichia*, *Neisseria*, the

The species *Streptococcus sobrinus* (arrows) appears darker from a specific staining technique. (b) Higher-magnification micrograph showing a region in the plaque with *S. sobrinus* cells (dark, arrow). Note the extensive capsule (lighter grey area) surrounding the *S. sobrinus* cells. (c) Light micrograph of a *Streptococcus mutans* culture showing the characteristic cell chains of streptococci. (d) Scanning electron micrograph of the sticky dextran material that holds cells together in filaments. Individual cells of both *S. sobrinus* and *S. mutans* are about 1 μm in diameter.

filamentous anaerobe *Fusobacterium*, and many others (Figure 25.8). Moreover, the different species likely play specific structural and functional roles in mature dental plaque. This can be seen in FISH-stained (Section 19.5) sections of plaque, where filamentous streamers of cells of *Corynebacterium* attached to a thin biofilm on the tooth surface anchor cells of *Streptococcus* and other bacteria a short distance away from the tooth surface (Figure 25.8). Such an arrangement probably allows *Streptococcus* cells to extend out from the tooth surface into regions of the oral cavity where saliva, sugars, and other nutrients are more abundant.

Dental plaque is thus a complex mixed-culture biofilm composed of several different genera of *Bacteria* and their accumulated products. A few *Archaea* are also present in dental plaque, primarily methanogenic species such as *Methanobrevibacter oralis*. As dental plaque accumulates, the microbiota secrete locally high concentrations of lactic acid that decalcifies tooth enamel, resulting in dental caries. Tooth enamel is strongly calcified tissue, and the ability of microbes to invade this tissue plays a major role in the extent of

dental caries and related, often more serious, oral pathologies, including *gingivitis* and *periodontitis*, bacterial diseases that erode the tooth-supporting gum and bone tissues.

Invasion and Systemic Infection

In the case of dental caries, the bacterial infection primarily resides on the tooth and gum surfaces. By contrast, in most infectious diseases, the pathogen must invade past the tissue surface in order to promote disease. **Invasion** is the ability of a pathogen to enter into host cells or tissues, spread, and cause disease. Some pathogens remain localized after initial entry, multiplying and invading at a single focus of infection, such as the boil that may arise from *Staphylococcus* skin infections (Section 31.9). However, sometimes the pathogens enter the bloodstream, from where they can travel to distant parts of the body. Depending on the pathogen and the condition of an individual and that individual's immune system, the presence of bacteria in the blood can have mild or highly severe consequences.

The mere presence of bacteria in the blood is called **bacteremia**; this condition is typically self-limiting and asymptomatic, as the bacterial cells do not grow in the bloodstream, and the immune system quickly removes them. By contrast, in **septicemia** bacteria multiply in the bloodstream, and the organism spreads systemically

Figure 25.8 Bacterial diversity of dental plaque. Confocal micrograph of a FISH-stained (Section 19.5) section through human dental plaque using a suite of phylogenetic probes containing different fluorescent tags. Color matching to specific groups is shown below the photo. The tooth surface would be on the left with the filamentous *Corynebacterium* species (purple) containing attached streptococci (green) flaring out from an attachment site on the tooth surface.

from an initial focus and produces toxins or other poisonous substances. Septicemia usually begins as an infection in a specific organ such as the intestine, kidney, or lung, and then spreads rapidly throughout the body from there. Septicemia is typically associated with major symptoms and may lead to massive inflammation, culminating in septic shock (sepsis) and death. *Viremia* is the term used to describe viruses present in the bloodstream, and measles, a highly infectious disease in those not vaccinated (► Section 31.6), is a good example of a systemic viremia.

A pathogen that causes disease in a given host can trigger mild or severe outcomes depending on its inherent capacity to elicit disease. We consider the principles that govern these capacities now with a focus on the important infectious disease concept called *virulence*.

Check Your Understanding

- At what body sites do pathogens typically attach and colonize?
- How does the capsule of *Streptococcus mutans* assist in the formation of dental caries?
- Which is the more serious condition, bacteremia or septicemia, and why?

25.3 Pathogenicity, Virulence, and Virulence Attenuation

Unique properties of each pathogen contribute to its **pathogenicity**, the overall ability to cause disease. The measure of pathogenicity is called **virulence**, the relative ability of a pathogen to cause disease. Pathogenicity and virulence are not uniform properties of a given pathogen and can differ dramatically between different strains of the same bacterial species or virus. Highly virulent strains of a given pathogen tend to emerge every so often and when they do, they often trigger a particularly severe course of disease that is rapid and widespread, potentially resulting in an epidemic or pandemic (Chapter 30). The virulence of a given pathogen depends on a number of factors including its relative abilities to adhere, colonize, and invade (Figure 25.1), as well as its arsenal of virulence factors.

Virulence

Virulence is the net outcome of host–pathogen interactions, a dynamic relationship between the two organisms influenced by ever-changing conditions in the pathogen, the host, and the environment. Host damage in an infectious disease is mediated by **virulence factors**, toxic or destructive substances produced by the pathogen that directly or indirectly enhance invasiveness and host damage by facilitating and promoting infection. The second part of this chapter is devoted to major virulence factors.

Virulence is a quantifiable entity, especially if a pathogen is lethal and an experimental animal model is available. For example, the LD₅₀ (LD stands for “lethal dose”) is defined as the number of cells of a pathogen (or virions, for a viral pathogen) that kills 50% of the population of the host organism in a test group. Highly virulent pathogens frequently show little difference in the number of cells required to kill 100% of a test group as compared with the LD₅₀. To illustrate this, recall the foundational work of the British microbiologist Frederick Griffith (◀ Section 1.14 and Figure 1.38). Griffith worked with the gram-positive bacterium *Streptococcus pneumoniae*

and discovered that strains of *S. pneumoniae* that contained a capsule (“smooth” strains because they formed smooth colonies on plates) were highly virulent for mice, whereas mutant derivatives lacking a capsule (“rough” strains) were not. The *S. pneumoniae* capsule is the primary virulence factor of this bacterium because it helps the bacterium evade immune surveillance. Griffith’s key discovery was that the smooth phenotype could be transferred to rough cells by treating rough cells with an extract from smooth cells (◀ Figure 1.38). This was the first experimental example of transformation, a bacterial genetic transfer process (◀ Section 9.6), and the transforming constituent in the extract was later shown (by other scientists) to be DNA.

Griffith’s choice of experimental organism was fortuitous because *S. pneumoniae* is both readily transformable and highly virulent for mice. Only a few cells of an encapsulated strain of *S. pneumoniae* can establish a fatal infection and kill all mice in a test population. As a result, the LD₅₀ for *S. pneumoniae* in mice is not proportional to the number of cells delivered (Figure 25.9). By contrast, the number of cells of a less virulent pathogen, such as the gram-negative enteric bacterium *Salmonella enterica* (*typhimurium*), necessary to kill all of the mice in the test population is about 10,000-fold greater than the highly virulent *S. pneumoniae* cells, and the LD₅₀ is proportionally related to the number of cells of the pathogen injected into the mice (Figure 25.9).

There are many examples of highly virulent human pathogens, especially among viruses. For example, some strains of the influenza virus are so highly virulent that only a few virions can initiate

Figure 25.9 Microbial virulence. Differences in microbial virulence demonstrated by the number of cells of *Streptococcus pneumoniae* (red bars) and *Salmonella enterica* (*typhimurium*) (green bars) required to kill mice. A colorized scanning electron micrograph of each bacterium is shown above its respective graph.

Mastering
Microbiology
Art Activity:
Figure 25.9
Microbial
virulence

disease even though mortality rates are typically low. Ebola virus is also highly virulent, and the tiny inoculum necessary to initiate disease often results in a fatal infection. By contrast, the bacterial pathogen *Vibrio cholerae* (which causes cholera) is not especially virulent, as a large inoculum of this intestinal pathogen is necessary to initiate disease (► Section 33.3).

Attenuation

The virulence of a pathogen can change. *Attenuation* is the decrease or loss of virulence of a pathogen (Figure 25.10). When pathogens are kept in laboratory culture rather than isolated from diseased animals, their virulence often decreases, or may be completely lost. Strains that have either a reduced virulence or are no longer virulent are said to be **attenuated**. Attenuation is thought to occur because nonvirulent or weakly virulent mutants grow faster than virulent strains in laboratory media where virulence has no selective advantage. After successive transfers in fresh media, such mutants are therefore selectively favored. However, if an attenuated culture is reinoculated into an animal, the organism may regain its original virulence, especially with continued *in vivo* passage as more-virulent strains are naturally selected. In some cases, though, the loss of virulence is permanent. For example, if a deletion mutation led to a major modification of a required receptor molecule (Figure 25.2b) or to the inability to produce a key virulence factor, such as the production of a toxin or invasive enzyme, then the mutant strain would be permanently attenuated.

Attenuated strains of various pathogens are valuable to clinical medicine because they are often used for the production of vaccines, especially viral vaccines. This principle was first demonstrated in the 1880s by Louis Pasteur with his remarkable development of the first rabies vaccine (◄ Section 1.11 and Figure 1.32a), and since that time, attenuated viral strains have also been employed in the production of vaccines for measles, mumps,

rubella, chicken pox/shingles, and yellow fever (Figure 25.10). Although attenuated viruses are “live” in the sense that, unlike “killed” strains, they are capable of replication and could in principle become virulent once again, properly attenuated virus vaccines (those free of any unattenuated virions) typically show greater efficacy and generate an overall stronger immune response than do killed virus vaccines.

Check Your Understanding

- What are virulence factors? How can the LD₅₀ test be used to define virulence of a pathogen?
- What circumstances can contribute to attenuation of a pathogen?

25.4 Genetics of Virulence and the Compromised Host

The virulence of a bacterial pathogen and the eventual outcome of an infectious disease are the net result of genetic and physiological features of both the pathogen and the host. In the case of the host, a pathogen may infect a healthy, well-rested young adult or an individual compromised by an ailment, such as a physiological condition (old age, hospitalization, immune suppression), an ongoing infectious disease (for example, acquired immunodeficiency syndrome [AIDS] caused by the human immunodeficiency virus [HIV]), or a genetic disease (for example, cystic fibrosis). The outcome of infection—health or disease—may be very different in these different individuals, even if they are infected by the same strain of a viral or bacterial pathogen.

Figure 25.10 Attenuation of virulence in vaccine production. To produce the yellow fever vaccine, the isolated virus is attenuated by dozens of passages in hosts that are increasingly dissimilar to the original human host, with the final preparation occurring in embryonated chicken eggs. With each successive passage, the virus gradually becomes more adapted to its new host, while simultaneously becoming less virulent to the original human host. When introduced to a susceptible individual, the weakened viral strain elicits a protective immune response to yellow fever without causing symptoms of the disease itself.

The virulence of a pathogen may be encoded by firmly entrenched chromosomal genes or by highly mobile genetic elements. For example, the gram-negative bacterium *Bordetella pertussis*, the causative agent of whooping cough (pertussis, ► Section 31.3), makes several toxins including pertussis toxin, a potent AB-type exotoxin (Section 25.6); collectively, these toxins trigger the symptoms of whooping cough. Other species of *Bordetella* do not make pertussis toxin, and the chromosomal gene encoding pertussis toxin does not readily move from *B. pertussis* to other species. But in contrast to *B. pertussis*, some bacterial pathogens routinely exchange genes encoding virulence factors with different bacterial species or even genera, and thus highly related versions of their most potent weapons may appear in several different pathogens. *Salmonella* is a well-studied example of the genetic transfer of virulence factors, and we focus on this bacterium now.

Virulence in *Salmonella*: Pathogenicity Islands and Plasmids

Salmonella species infect humans, leading to various gastrointestinal illnesses (► Section 33.10), and they encode a large number of virulence factors that are important in disease. These include type I fimbriae (Section 25.1) to facilitate attachment of cells to gastrointestinal tissues; several different classes of exotoxins (Section 25.6); antiphagocytic proteins that block engulfment of bacterial cells by host phagocytes; proteins that promote survival if the bacterium does get phagocytosed; siderophores, organic molecules that bind iron tightly and, in pathogenic bacteria, allow the bacteria to outcompete host sequestration systems for iron; and endotoxin (Section 25.8). With the exception of endotoxin, many of these virulence factors are encoded by genes present on mobile DNA rather than on the cell's chromosome (Figure 25.11).

Figure 25.11 Virulence factors in *Salmonella*. Factors important for virulence and the development of pathogenesis in this gram-negative enteric pathogen are shown. Genes encoding many of the factors reside on the pathogenicity islands or plasmids.

Several genes that encode these virulence factors in *Salmonella* and related gram-negative pathogens, such as pathogenic strains of *Escherichia coli* (► Section 33.11), are found clustered together on the chromosome as *pathogenicity islands*. *Salmonella* pathogenicity island 1 (SPI1) is a cluster of genes that encodes over 10 distinct proteins that promote virulence and invasion. One of these is *invH*, a gene encoding a surface adhesion protein (Section 25.1). Several *inv* genes encode proteins important for trafficking of virulence factors. For example, the *InvJ* regulator protein controls assembly of structural proteins *InvG*, *PrgH*, *PrgL*, *PrgI*, and *PrgK*, which form a type III secretion system called the *injectisome*, an organelle in the bacterial envelope that allows for the direct transfer of virulence proteins into host cells through a needle-like assembly (◄ Section 6.13 and Figures 6.43 and 6.44).

A second *Salmonella* pathogenicity island, SPI2, contains genes that are responsible for causing more systemic than localized disease and resistance to host defenses. In addition, several plasmid-encoded virulence factors, such as antibiotic resistance genes encoded on R plasmids (◄ Section 6.2), can spread between *Salmonella* species and other genera of enteric bacteria. Pathogenicity islands and R plasmids allow for the facile and rapid transfer of virulence factors. It is thus not uncommon for genes encoding factors in one pathogen to be similar, if not identical, to those in another because of transfer of parts or all of the islands or plasmids between species by horizontal gene exchange (Chapter 9).

In the well-known opportunistic pathogen (see next subsection) *Pseudomonas aeruginosa*, pathogenicity islands can also contain genes encoding antibiotic resistance. As for *Salmonella*, many cases of multiple antibiotic resistance in *P. aeruginosa* are linked to plasmids. However, in some strains of *P. aeruginosa*, genomic islands containing transposable elements (◄ Section 9.11) are present. By transposition these islands have “captured” multiple antibiotic resistance genes and can then disseminate them to other organisms; the genomic islands are present in *P. aeruginosa* in place of or in addition to resistance plasmids. Regardless of how they are encoded, these strains have become resistant to virtually all of the clinically useful antibiotics that have traditionally been used to control *P. aeruginosa* infections. This is a particularly serious problem for the compromised host and in the hospital environment, and we consider these issues now.

The Compromised Host

Some individuals are simply more susceptible to infection than others for reasons that have little to do with the virulence of the pathogen. These so-called *compromised hosts* are individuals in which one or more mechanisms of resistance to disease are inactive and in whom the probability of infection is therefore increased. Many hospital patients with noninfectious diseases (for example, cancer and heart disease) acquire microbial infections more readily because they are compromised hosts. Such *healthcare-associated infections* (also called *nosocomial infections*; ► Section 29.2) affect up to 2 million individuals each year in the United States, with a nearly 5% mortality rate. Invasive medical procedures such as catheterization, hypodermic injection, spinal puncture, biopsy, and surgery may unintentionally introduce

Mastering
Microbiology
Art Activity:
Figure 25.10
Virulence
factors in
Salmonella

microorganisms into the patient. The stress of surgery and the anti-inflammatory drugs given to reduce pain and swelling can also reduce host resistance.

Some factors can compromise host resistance outside the hospital, including lifestyle choices that affect major organs of the body, such as intravenous drug usage, tobacco use, and excessive consumption of alcohol, or genetic diseases that eliminate parts of the immune system (▶ Section 28.2). People that are physically compromised for any of a number of reasons may be more susceptible to infections, not only because they are physically weakened but also because their living conditions and lifestyle choices may put them in more continual contact with infectious agents. For example, infection with the human immunodeficiency virus (HIV) predisposes an individual to infections from **opportunistic pathogens**, microbes that cause disease only in the absence of normal host resistance. HIV causes AIDS by destroying a specific class of immune cell, the CD4 T lymphocytes (▶ Section 31.15), which are key to an effective immune response. The reduction in CD4 T cells reduces immunity, and an opportunistic pathogen—one that does not cause disease in a healthy, uninfected host—can then cause serious disease or even death. Individuals with immunodeficiencies from underlying genetic causes rather than infection are also more susceptible to opportunistic infections because part of their immune system is either nonfunctional or suboptimal.

The outcome of an infectious disease thus depends on several factors, both host and pathogen related. Two individuals exposed to the same pathogen in the same way may well show different outcomes. But once an infection has proceeded to the actual stage of disease, the symptoms that appear are due to harmful products of the pathogens, and we turn our attention to these now.

- What is a nosocomial infection?

II • Enzymes and Toxins of Pathogenesis

Many pathogenic microbes increase their competitiveness by synthesizing potent products—enzymes and toxins—that allow them to access nutrients in the host. These virulence factors may help the pathogen in initial invasion, be the final result of successful colonization, or be secreted into food or other nonliving substances later ingested by the host.

Bacterial pathogens damage host tissues (or the entire host) in two major ways: (1) by secreting tissue-destroying enzymes and (2) by secreting or shedding toxins that target specific host tissues or the entire host. In contrast to bacterial pathogens, most viral pathogens damage host tissues by lysing cells directly, although some viruses are nonlytic and instead introduce genes into host cells that may eventually harm the host (◀ Section 5.7).

We turn our focus now to the enzymes and toxins of well-studied pathogenic bacteria, contrasting their potency and modes of action. Some of these virulence factors cause only minor disease symptoms, whereas others are among the most poisonous substances known.

25.5 Enzymes as Virulence Factors

Following adherence, colonization, and infection by a pathogen, invasiveness requires the breakdown of host tissues and access to nutrients released from host cells. In many classical bacterial pathogens, this is accomplished through the activity of *enzymes* that attack and destroy cells in one type of tissue or another (Table 25.1).

Tissue-Destroying Enzymes

Many virulence factors are enzymes. For example, streptococci, staphylococci, and certain clostridia produce *hyaluronidase* (Table 25.1), an enzyme that promotes spreading of organisms in tissues by breaking down the polysaccharide hyaluronic acid. Among other functions, hyaluronic acid is a component of the extracellular matrix and functions as a type of “intercellular cement” in animal connective tissues, helping to maintain the organization of

TABLE 25.1 Enzyme virulence factors of some well-known gram-positive bacterial pathogens			
Organism	Disease	Enzyme ^a	Enzyme activity
<i>Staphylococcus aureus</i>	Pus-forming infections	Coagulase	Induces fibrin clotting; allows bacterial cells to remain at site of infection (prevents access to pathogens by cells of the immune response)
		Nuclease; lipase	Break down nucleic acids or lipids
<i>Streptococcus pyogenes</i>	Pus-forming infections; scarlet fever; strep throat	Hyaluronidase	Dissolves hyaluronic acid in connective tissues; allows bacterial cells to spread (enhances pathogen invasion)
		Streptokinase	Dissolves fibrin clots; allows bacterial cells to spread
<i>Clostridium perfringens</i>	Gas gangrene; food poisoning	Collagenase	Breaks down collagen (a protein), allowing the bacterium to spread to other tissues
		Protease	Breaks down proteins

^aThe activities of coagulase, hyaluronidase, and streptokinase are depicted in Figure 25.12.

individual cells into tissues. The activity of hyaluronidase causes host cells to slough apart, allowing pathogens at an initial colonization site to spread between host cells to attack subsurface tissues (Figure 25.12a). Similarly, the clostridia that cause gas gangrene produce *collagenase*, an enzyme that destroys collagen (a major protein of connective tissues in muscle and other body tissues); collagenase enables these bacteria to gain access to deeper host tissues and spread through the body. Recall that clostridia are anaerobes, and colonizing deeper tissues allows them to reach less oxidic conditions and provides a ready source of nutrients from destroyed tissues (gangrene clostridia are typically proteolytic species, ◀ Section 16.8 and ▶ Section 32.9). Many pathogenic streptococci and staphylococci also produce proteases, nucleases, and lipases that degrade host proteins, nucleic acids, and lipids, respectively (Table 25.1).

Two virulence factors are enzymes that affect fibrin, the insoluble blood protein that triggers blood clots, but the activities of the enzymes yield opposing results (Figure 25.12b). Blood clotting is triggered by tissue injury and functions not only to stop blood loss but also, in the case of a bacterial infection, to isolate the pathogen, limiting the infection to a local region. Some pathogens counter this host protective mechanism by producing fibrinolytic enzymes, such as *streptokinase* produced by *Streptococcus pyogenes*. This bacterium is often associated with pus-forming wounds and secretes

streptokinase to dissolve fibrin clots and make further invasion possible (Table 25.1, Figure 25.12b). Streptokinase specifically activates the host to produce plasmin, an enzyme that degrades fibrin blood clots. Because of this powerful activity, streptokinase also has a medically beneficial function. The protein is marketed as a pharmaceutical and administered intravenously to dissolve clots for conditions in which normal blood flow is blocked by blood clots, such as from heart attacks, deep vein thromboses, or embolisms.

In contrast to the fibrin-destroying activity of streptokinase, some pathogens produce enzymes that actually *promote* the formation of fibrin clots. These clots protect the pathogen from host responses. For example, *coagulase* (Table 25.1), produced by virulent *Staphylococcus aureus*, converts fibrinogen to fibrin, resulting in the clotting of blood and the formation of fibrin surrounding the *S. aureus* cells; this blanket of fibrin protects the *S. aureus* cells from attack by cells of the host's immune system (Figure 25.12b). The fibrin matrix produced as a result of coagulase activity may also account for the localized nature of many staphylococcal infections, as is typically seen in boils and pimples (▶ Section 31.9). Coagulase-positive *S. aureus* strains are typically more virulent than coagulase-negative strains, a likely reflection of the former's ability to evade innate immune responses such as phagocytosis (Chapter 26) and continue growth and tissue destruction for a longer period.

Enzyme Activities at the Host's Mucosal Surface

Host mucosal surfaces are bathed in immune substances including enzymes such as lysozyme, an enzyme that cleaves the peptidoglycan of bacterial cells and promotes their osmotic lysis (◀ Section 2.3). Virulence factors produced by the gram-positive bacterium *Enterococcus faecalis*—a major cause of bacteremia, surgical wound infections, and urinary tract infections—subvert the protective role of lysozyme by altering the structure of the bacterium's peptidoglycan such that lysozyme can no longer recognize its substrate.

Antibodies are also present on mucosal surfaces, in particular a class of antibody called IgA (▶ Section 27.3). These “secretory antibodies,” as they are called, help prevent pathogen adherence to host tissues (Section 25.1). However, certain pathogenic bacteria counter this protective role by producing enzymes that specifically cleave IgA (IgAases), rendering this host defense useless; *Neisseria* species such as *N. gonorrhoeae* (gonorrhea) and *N. meningitidis* (meningitis) are particularly notorious in this regard.

We thus see that pathogens can produce enzymes both as offensive weapons—to destroy host tissues—and as defensive weapons—to destroy or inactivate defensive weapons of the host. Both strategies accomplish a similar objective: The invasiveness of the pathogen is increased, and this allows it to ultimately extract more resources from its host.

Figure 25.12 Activity of some enzyme virulence factors. (a) Hyaluronidase. (b) Coagulase (left) and streptokinase (right). Along with some other bacterial pathogens, virulent strains of *Streptococcus pyogenes* typically produce hyaluronidase and streptokinase, and virulent strains of *Staphylococcus aureus* typically produce coagulase.

- What is an IgAase, and why would a bacterial pathogen produce one?

25.6 AB-Type Exotoxins

Toxicity is the ability of an organism to cause disease by means of a toxin that inhibits host cell function or kills host cells (or the host itself). **Exotoxins** are toxic *proteins* secreted by the pathogen as it grows. These toxins travel from a site of infection and cause damage at distant sites. Some exotoxins are **enterotoxins**, toxic proteins whose site of action is the small intestine, generally causing secretion of fluid into the intestinal lumen, resulting in vomiting and diarrhea. Exotoxins fall into three categories in terms of their mechanism: *AB toxins*, *cytolytic toxins*, and *superantigen toxins*. In this section we consider the AB toxins, and in Section 25.7 we focus on cytolytic and superantigen toxins.

As the name implies, AB toxins consist of two subunits, A and B. The B component binds to a host cell surface molecule, facilitating the transfer of the A subunit across the cytoplasmic membrane, where it damages the cell. Some of the best-known and most potent exotoxins are AB toxins, including those expressed in diphtheria, tetanus, botulism, and cholera (Table 25.2).

Diphtheria Exotoxin: Blockage of Protein Synthesis

The diphtheria toxin produced by the aerobic gram-positive bacterium *Corynebacterium diphtheriae* is an AB toxin and an important virulence factor of the pathogen (► Section 31.3). Diphtheria toxin

inhibits protein synthesis in eukaryotic cells. Rats and mice are relatively resistant to diphtheria toxin, whereas humans are very susceptible, with only a single molecule of toxin sufficient to kill a cell. Diphtheria has a significant mortality rate, especially in the young, and death ensues from tissue destruction in vital organs such as the heart and liver as diphtheria toxin blocks protein synthesis.

Cells of *C. diphtheriae* secrete diphtheria toxin as a single polypeptide. One component of the toxin, subunit B, specifically binds to a host cell receptor protein on eukaryotic cells, the heparin-binding epidermal growth factor (Figure 25.13). After binding, proteolytic cleavage between subunit B and the remaining portion of the protein, subunit A, allows subunit A to move across the host cytoplasmic membrane into the cytoplasm. Here subunit A disrupts protein synthesis by blocking transfer of an amino acid from tRNA to growing polypeptide chains. Diphtheria toxin specifically inactivates elongation factor 2 (EF-2), a protein that functions in growth of the polypeptide chain, by catalyzing the attachment of adenosine diphosphate (ADP) ribose from NAD⁺. Following ADP-ribosylation, the activity of the modified EF-2 decreases dramatically, and protein synthesis stops (Figure 25.13).

Diphtheria toxin is not encoded by the bacterium but instead by a viral gene called *tox* present in the genome of the lysogenic bacteriophage β . Lysogenic phages are those whose genomes have become

Figure 25.13 The activity of diphtheria toxin. Diphtheria toxin, an AB toxin produced by cells of *Corynebacterium diphtheriae*, binds to the host cytoplasmic membrane by way of its B subunit. Cleavage of the toxin allows the A subunit to enter the cell where it catalyzes ADP-ribosylation of elongation factor 2 (EF-2), a key factor in translation. The modified elongation factor no longer binds to the ribosome, resulting in the cessation of protein synthesis and host cell death. Inset photo: Light micrograph of Gram-stained cells of *Corynebacterium diphtheriae*. A single cell is about 0.75 μm in diameter.

integrated into their host's chromosome (◀ Section 5.6). Toxigenic, pathogenic strains of *C. diphtheriae* are infected with phage β and hence produce the toxin. Nontoxigenic, nonpathogenic strains of *C. diphtheriae* can be converted to pathogenic strains by infection with phage β , a process called *phage conversion* (◀ Section 9.7).

Exotoxin A of *Pseudomonas aeruginosa* functions similarly to diphtheria toxin, also modifying EF-2 by ADP-ribosylation. The enterotoxin produced by *Shigella dysenteriae*, called *Shiga toxin*, and the Shiga-like toxin produced by enteropathogenic *Escherichia coli* O157:H7 (▶ Section 33.11) are also AB toxins (Table 25.2). Shiga and Shiga-like toxins target cells of the small intestine near where the pathogen colonized, shutting down protein synthesis. This leads to cell death, bloody diarrhea, and hemolytic uremic syndrome, a kidney disease that can trigger kidney failure, especially in children.

Neurological Exotoxins: Botulinum and Tetanus Toxins

Clostridium botulinum and *Clostridium tetani* are endospore-forming bacteria commonly found in soil and which cause the serious and potentially fatal diseases botulism and tetanus, respectively; both

diseases are caused by the secretion of highly poisonous AB exotoxins that function as *neurotoxins* (▶ Sections 32.9 and 33.9). Neither *C. botulinum* nor *C. tetani* is highly invasive, and therefore pathogenicity is almost exclusively due to neurotoxicity.

C. botulinum sometimes grows directly in the intestine, causing infant or wound botulism. Most frequently for adults, however, botulism results from cells of *C. botulinum* growing and producing toxin in improperly preserved foods, such as home-canned vegetables. Thus, infection and growth of the pathogen in the body are unnecessary. Botulinum toxins consist of seven related but distinct AB toxins, and of these, at least two are encoded on lysogenic bacteriophages specific for *C. botulinum*. Botulinum toxin and tetanus toxin both block the release of neurotransmitters that control muscle activities, but as we will see, the mode of action and symptoms of botulism and tetanus are quite distinct.

Normal transmission of a nerve impulse to a muscle cell at a neuromuscular junction requires interaction of the neurotransmitter acetylcholine with a muscle receptor (Figure 25.14a). Botulinum toxins, which consist of both a heavy chain that binds the neuronal surface and a light-chain endopeptidase, prevent this interaction. After binding the motor end plate—the presynaptic membrane on the terminus of the stimulatory motor neuron—the toxin enters the cell by endocytosis. The heavy chain of the toxin then translocates the light chain across the vesicle membrane into the cytoplasm of the neuron. Depending upon which of the seven forms of botulinum toxin has entered the cell, the proteolytic light chain then cleaves any of several proteins that coordinate release of the

Figure 25.14 The activity of botulinum toxin. (a) Upon stimulation of peripheral and cranial nerves, acetylcholine (A) is normally released from vesicles at the neural side of the motor end plate. Acetylcholine then binds to specific receptors on the muscle, inducing contraction. (b) Botulinum toxin acts at the motor end plate to prevent release of acetylcholine from vesicles, resulting in a lack of stimulus to the muscle fibers, irreversible relaxation of the muscles, and flaccid paralysis.

enterotoxin

neurotransmitter into the synaptic space, thus blocking the excitatory acetylcholine signal and preventing muscle contraction (Figure 25.14b). This is recognized as *flaccid paralysis* in a botulism victim, and it can lead to death by suffocation if the diaphragm muscles are severely affected.

Botulinum toxins are the most potent biological substances known; just one nanogram (10^{-9} g) of botulinum toxin is sufficient to kill a guinea pig. Thus, it is perhaps surprising that botulinum toxins have proved beneficial in the treatment of chronic pain. Because chronic pain, such as that associated with ongoing back and neck pain or frequent migraines, is often caused by neuropathy or stress-induced muscle tension, low-dose injections of dilute botulinum toxin (Botox®) can relax the affected tissues and effectively mitigate pain. This is especially useful considering that botulinum toxin treatments are not linked to the unwanted side effects that commonly accompany traditional drug treatments for these conditions.

In contrast to *C. botulinum*, *C. tetani* grows in the body in deep wounds that become anoxic, such as punctures. *C. tetani* cells rarely leave the wound where they were first introduced, growing relatively slowly at the wound site. On contact with the nervous system, tetanus toxin, called *tetanospasmin*, is transported through the motor

neurons to the spinal cord, where it binds specifically to ganglioside lipids at the termini of the inhibitory interneurons (Figure 25.15). The inhibitory interneurons normally work by releasing an inhibitory neurotransmitter, typically the amino acid glycine, which binds to receptors on the motor neurons. Glycine from the inhibitory interneurons then stops the release of acetylcholine by the motor neurons and inhibits muscle contraction, allowing relaxation of the muscle fibers. However, if tetanus toxin blocks glycine release, the motor neurons cannot be inhibited, resulting in the continual release of acetylcholine and uncontrolled contraction of the muscle fibers (Figure 25.15b). Thus, in contrast to botulinum toxin, which prevents muscle contraction (Figure 25.14), tetanus toxin prevents muscle relaxation (Figure 25.15).

The outcome in a case of tetanus is a twitching, *spastic paralysis*—the hallmark of tetanus (► Section 32.9 and Figure 32.23b)—as affected muscles are constantly contracting. If the muscles of the mouth are involved, as is commonly the case, the prolonged contractions restrict the mouth's movement, resulting in a condition called *lockjaw*. If the diaphragm is affected, its prolonged contraction may result in death due to asphyxiation.

Cholera Enterotoxin: Intestinal Distress

Cholera enterotoxin is an AB-type exotoxin produced by *Vibrio cholerae*, the causative agent of the waterborne disease cholera (► Section 33.3). Cholera is characterized by massive fluid loss from the intestines, resulting in severe diarrhea, life-threatening dehydration, and electrolyte depletion (Figure 25.16). Cholera starts by ingestion of *V. cholerae* cells from food or water contaminated with human feces. The organism travels to the small intestine, where it colonizes and secretes cholera toxin. In the small intestine, the B subunit of cholera toxin, consisting of five identical monomers, binds specifically to GM1 ganglioside, a complex glycolipid found in the cytoplasmic membrane of intestinal epithelial cells (Figure 25.16).

The B subunit targets cholera toxin specifically to receptors in the intestinal epithelium but has no toxicity itself; toxicity is a function of the A subunit, which crosses the cytoplasmic membrane and activates adenylate cyclase, the enzyme that converts ATP to cyclic adenosine monophosphate (cAMP). This molecule is a cyclic nucleotide (◄ Figure 7.22) that mediates several regulatory systems in cells, including ionic balance. The increased cAMP induced by cholera enterotoxin blocks Na^+ uptake by small intestine epithelial cells and induces secretion of chloride and bicarbonate (HCO_3^-) into the intestinal lumen. This change in ion concentrations leads to the secretion of large amounts of water; the rate of water loss into the small intestine is greater than the possible reabsorption of water by the large intestine, resulting in a large net fluid loss and watery diarrhea. If untreated, cholera victims can die within hours of the major onset. However, if lost fluids are replaced with an oral rehydration solution (the main treatment for cholera), the effects of cholera toxin can be neutralized, and a cholera victim can return to normal in just a few days.

A few other enterotoxins, most notably the Shiga-like toxin of enterotoxigenic strains of *Escherichia coli* (► Section 33.11) and enterotoxins of *Shigella* and *Salmonella*, are also of the AB type (Table 25.2), and all of these function by inhibiting protein synthesis. This leads to major bouts of diarrhea, typically bloody and foul smelling, and

Figure 25.15 The activity of tetanus toxin. (a) Muscle relaxation is normally induced by glycine (G) release from inhibitory interneurons. Glycine acts on the motor neurons to block excitation and release of acetylcholine (A) at the motor end plate. (b) Tetanus toxin binds to the interneuron to prevent release of glycine from vesicles, resulting in a lack of inhibitory signals to the motor neurons, constant release of acetylcholine to the muscle fibers, irreversible contraction of the muscles, and spastic paralysis. For the purpose of illustration, the inhibitory interneuron is shown near the motor end plate, but it is actually in the spinal cord.

severe dehydration. In addition, some cytolytic enterotoxins are known, and the powerful enterotoxins of *Staphylococcus aureus* (Table 25.2) are of the superantigen type. We consider these dangerous toxins now.

1. Normal ion movement, Na^+ from lumen to blood, no net Cl^- movement

2. Infection and toxin production by *V. cholerae*

3. Activation of epithelial adenylate cyclase by cholera toxin

4. Elevated cAMP blocks Na^+ ; net anion movement to intestinal lumen

5. Massive water movement to the lumen and ion loss trigger cholera symptoms.

Figure 25.16 The activity of cholera enterotoxin. Cholera toxin is an AB enterotoxin that activates a second-messenger pathway, disrupting normal ion flow in the intestine, resulting in potentially life-threatening diarrhea. The thumbnail photo of the three-dimensional structure shows a side view of the toxin, with the separate cell-binding B subunit and the enzymatically active A subunit.

- Why do botulism and tetanus show such opposing symptoms?

25.7 Cytolytic and Superantigen Exotoxins

The pathogenesis of exotoxins such as the cytolytic and superantigen toxins differs from those of the classical AB toxins. Cytolytic and superantigen exotoxins function by destroying host cells, such as from the activity of hemolysins, or by triggering a massive immune response, such as in the case of toxic shock exotoxin, the cause of toxic shock syndrome. As for other exotoxins, however, these proteins are produced by the pathogen to increase its invasiveness and release host cell resources that can benefit the pathogen.

Cytolytic Exotoxins

Cytotoxins (also called cytolytic exotoxins) are soluble proteins secreted by a variety of pathogens (Table 25.2). Cytotoxins damage the host cytoplasmic membrane, causing cell lysis and death. Because the lytic activity of these toxins is most easily observed in assays that use red blood cells (erythrocytes), the toxins are often called *hemolysins* (Table 25.2). However, hemolysins also lyse cells other than erythrocytes. The production of hemolysins can be demonstrated by streaking the pathogen on a blood agar plate (a rich medium containing 5% sterile blood). During growth of the colonies, hemolysin is released and lyses the surrounding red blood cells, releasing hemoglobin and creating a clear area, called a zone of *hemolysis*, around the growing colonies (**Figure 25.17a**).

Some hemolysins attack the phospholipid of the host cytoplasmic membrane. Because the phospholipid lecithin (phosphatidylcholine) is often used as a substrate, these enzymes are called *lecithinases* or *phospholipases*. An example is the α -toxin of *Clostridium perfringens*, a lecithinase that dissolves membrane lipids, resulting in cell lysis (Table 25.2, Figure 25.17b). Because the cytoplasmic membranes of all organisms contain phospholipids ($\blacktriangleleft$ Section 2.1), phospholipases can destroy bacterial as well as animal cell cytoplasmic

Figure 25.17 Hemolysis. (a) Zones of hemolysis around colonies of *Streptococcus pyogenes* growing on a blood agar plate. (b) Activity of lecithinase, a phospholipase, around colonies of *Clostridium perfringens* growing on an agar medium containing egg yolk, a source of lecithin. Lecithinase dissolves the cytoplasmic membranes of red blood cells, producing cloudy zones of hemolysis around each colony.

membranes. In the case of *C. perfringens*, a major cause of gas gangrene, the activity of its lecithinase helps destroy tissues and release proteins that are then fermented by the bacterium in energy metabolism. Since *C. perfringens* lecithinase is secreted immediately after synthesis and is unable to reenter the cell, the enzyme does not affect the phospholipids in *C. perfringens* cells.

Some hemolysins, however, are not phospholipases. Streptolysin O, a hemolysin produced by streptococci, affects the sterols of the host cytoplasmic membrane. *Leukocidins* lyse white blood cells and thereby decrease the host immune response. Staphylococcal α -toxin (Figure 25.18 and Table 25.2) destroys both nucleated cells and erythrocytes. To do this, the seven α -toxin subunits first bind to the phospholipid bilayer. The subunits then combine to form into nonlytic heptamers, now associated with the membrane. Each heptamer then undergoes conformational changes to produce a membrane-spanning pore that releases cytoplasmic contents and allows the influx of extracellular materials, thus killing the cell (Figure 25.18).

Superantigen Exotoxins

The gram-positive bacteria *Staphylococcus aureus* and *Streptococcus pyogenes* are major producers of exotoxin superantigens. We consider the mode of action of superantigens in Section 28.2 in the context of the immune response and focus here only on some basic disease symptoms.

Superantigen poisoning can be triggered by certain types of food poisoning (in particular, that caused by the enterotoxins of *S. aureus*), by toxic shock syndrome, or by pyrogenic fever (fever induced either from an internal source, such as small immune system proteins called cytokines, or from an external substance, such as endotoxin; see Section 25.8). Reactions to superantigen poisoning are severe and can even be fatal in some individuals, particularly

those whose immune systems and overall health are weakened from cancer, drug treatments, HIV infection, or old age. Toxic shock syndrome (TSS) is the classic example of the systemic effects of a toxic superantigen and results from exposure to any of a series of exotoxins secreted during infection by certain strains of *S. aureus* or *S. pyogenes* (► Sections 31.9 and 31.2, respectively).

S. aureus TSS commonly originates as a result of a localized rather than a generalized infection. By contrast, *S. pyogenes* TSS is typically the result of a systemic infection where bacteremia or septicemia (Section 25.2) is present, and tissue damage including extensive tissue necrosis occurs (► Figure 31.10); as a result, mortality rates from *S. pyogenes* TSS are considerably higher than from *S. aureus* TSS. In both cases, however, the symptoms of TSS are triggered when the immune system recognizes the superantigen toxin, but rather than activating just a small subset of T lymphocytes (key cells in adaptive immunity, Chapter 27) as usually occurs in the adaptive immune response, a large proportion of the entire T lymphocyte pool becomes activated. It is the structure of the superantigen itself that leads to this overblown immune response, a result of which is widespread release of cell-signaling cytokines and systemic inflammation that leads to hypotension (low blood pressure), intestinal disruption, organ failure, and eventually systemic shock.

In a clinical diagnosis, either staphylococcal or streptococcal TSS is suspected when an individual has a fever of 39°C or greater, systolic blood pressure of < 90 mm Hg, and functional disruption of three or more organ systems, most often gastrointestinal, kidney, and liver. In severe cases of TSS, intensive care hospitalization may be needed with intravenous administration of antibiotics.

Check Your Understanding

- Give an example of a cytolytic exotoxin and a superantigen exotoxin, as well as the bacteria that produce each.
- How can activity of a hemolytic exotoxin be detected?

Figure 25.18 Staphylococcal α -toxin. Staphylococcal α -toxin is a pore-forming cytotoxin that is produced by growing *Staphylococcus aureus* cells. Released as monomers, seven identical protein subunits oligomerize in the cytoplasmic membrane of target cells to form a pore, releasing the contents of the cell. In red blood cells, hemolysis occurs, visually indicating cell lysis. The inset image on the top left shows the structure of α -toxin looking down through the pore; each of the seven identical subunits is shown in a different color. The inset photo on the top right is a scanning electron micrograph of *S. aureus* cells.

25.8 Endotoxins

Endotoxins are the toxic lipopolysaccharides found in the cell walls of most gram-negative *Bacteria*. Endotoxins are not proteins but are structural components of the gram-negative outer membrane (◄ Section 2.4). In contrast to exotoxins, which are the secreted products of living cells, endotoxins are cell bound and released in toxic amounts only when the cells lyse. The basic properties of exotoxins and endotoxins are compared in Table 25.3.

Endotoxin Structure and Biology

A major component of the gram-negative cell outer membrane is lipopolysaccharide (LPS) (◄ Figures 2.12 and 2.13). LPS consists of three covalently linked subunits: the membrane-distal O-specific polysaccharide, a membrane-proximal core polysaccharide, and lipid A—a phosphoglycolipid and the membrane-anchoring portion of LPS (Figure 25.19). The lipid A portion of LPS is responsible for toxicity, whereas the polysaccharide fraction by itself is nontoxic. The polysaccharide functions to make the entire LPS complex soluble and immunogenic, and thus both the lipid and polysaccharide fractions must be delivered as a unit for toxicity to occur.

TABLE 25.3 Properties of exotoxins and endotoxins		
Property	Exotoxins	Endotoxins
Chemistry	Proteins, secreted by certain gram-positive or gram-negative <i>Bacteria</i> ; generally heat-labile	Lipopolysaccharide–lipoprotein complexes, released on cell lysis as part of the outer membrane of gram-negative <i>Bacteria</i> ; extremely heat-stable
Mode of action; symptoms	Specific; usually bind to specific cell receptors or structures; either cytotoxin, enterotoxin, or neurotoxin with defined, specific action on cells or tissues	General; fever, diarrhea, vomiting
Toxicity	Often highly toxic in picogram to microgram quantities, sometimes fatal	Moderately toxic in tens to hundreds of microgram amounts, rarely fatal
Immune response	Highly immunogenic; stimulate the production of neutralizing antibody (antitoxin)	Relatively poor immunogens; immune response not sufficient to neutralize toxin
Toxoid potential ^a	Heat or chemical treatment may destroy toxicity, but treated toxin (toxoid) remains immunogenic	None
Fever potential	Nonpyrogenic; do not produce fever in the host	Pyrogenic; often induce fever in the host
Genetic origin	Often encoded on extrachromosomal elements or lysogenic bacteriophages	Encoded by chromosomal genes

^aA toxoid is a modified toxin that is no longer toxic but can still elicit an immune response against the toxin (► Section 28.3).

Endotoxins have been well studied in the bacteria *Escherichia*, *Shigella*, and especially in *Salmonella*, where they are another of the many virulence factors that contribute to pathogenesis (Figure 25.11). The biosynthesis pathway of the toxic component of endotoxin, lipid A, is known and is a highly conserved process among gram-negative bacteria. Nevertheless, not all lipid A is structurally the same, as the molecule can be modified using enzymes that catalyze postsynthesis modifications that control the presence, absence, or number of phosphate groups, and the chemistry and number of fatty acid side chains (Figure 25.19). These subtle but important alterations affect the properties of the LPS molecule and are a virulence strategy that certain pathogens have evolved to either evade recognition by the host immune system or increase the toxicity of the molecule. However, some lipid A alterations affect toxicity in a negative way. For example, the phosphate groups (Figure 25.19)

are essential for binding lipid A to animal cell receptors, and although phosphate-free lipid A can evade immune surveillance, its toxicity is greatly reduced.

Endotoxins cause a variety of physiological effects. Fever is an almost universal result of endotoxin exposure because endotoxin stimulates host cells to release cytokines, soluble proteins secreted by certain cells of the immune system that function as *endogenous pyrogens*, proteins that affect the temperature-controlling center of the brain, causing fever. Cytokines released as a result of endotoxin exposure can also cause diarrhea, increased heart rate (tachycardia), a rapid decrease in the numbers of lymphocytes and platelets, and generalized inflammation (► Section 26.8). Other physiological consequences of endotoxin exposure include activation of the complement cascade (complement is a series of immune system proteins, ► Section 26.9), which also triggers inflammation, and activation of the blood coagulation cascade, which can lead to blood clots and reduced blood flow. Large doses of endotoxin can cause death from hemorrhagic shock and kidney failure.

Although significant virulence factors, endotoxins are generally less toxic than most exotoxins and rarely cause symptoms that can lead to death in an otherwise healthy individual if exposure is from a gastrointestinal source (Table 25.3). For instance, in mice the LD₅₀ (see Figure 25.9) for endotoxin is 200–400 *micrograms* per animal, whereas the LD₅₀ for botulinum exotoxin is about 25 *picograms*, about 10 million times less. By contrast, intravenous administration of endotoxin, for example from a heavily contaminated intravenous solution, could have fatal consequences, and we discuss how such faulty solutions can be identified now.

***Limulus* Amoebocyte Lysate Assay for Endotoxin**

Because endotoxins induce fever and can trigger other, more serious symptoms, pharmaceuticals such as injectable antibiotics and intravenous solutions must be free of endotoxin. An endotoxin assay of high sensitivity and specificity in widespread use employs lysates of

Figure 25.19 Endotoxin. Left to right: Scanning electron micrograph of cells of the gram-negative bacterium *Escherichia coli*; structure of the gram-negative cell wall including the lipopolysaccharide (LPS) outer membrane; detailed structure of lipid A, the toxic portion of LPS, along with part of the core polysaccharide of LPS.

Figure 25.20 *Limulus* amoebocyte assay for endotoxin. (a) Normal amoebocytes from the horseshoe crab *Limulus polyphemus*. (b) Amoebocytes following exposure to bacterial lipopolysaccharide (LPS). LPS induces degranulation and lysis of the cells.

amoebocytes from the horseshoe crab *Limulus polyphemus* (amoebocytes are mobile cells in the blood and fluids of invertebrates that are analogous to the white blood cells of vertebrates). Endotoxin specifically causes lysis of the amoebocytes (**Figure 25.20**). In the *Limulus* amoebocyte lysate (LAL) assay, *Limulus* amoebocyte extracts

are mixed with the solution to be tested. If endotoxin is present, the amoebocyte extract forms a gel and precipitates, causing a change in turbidity. This reaction is measured quantitatively with a spectrophotometer and can detect as little as 10 picograms of LPS in a 1-ml sample.

The LAL assay is also used to detect endotoxin in clinical samples such as serum or cerebrospinal fluid, and a positive result provides presumptive evidence for infection by gram-negative bacteria. Drinking water, water used for formulation of injectable drugs, and injectable aqueous solutions are routinely tested using the LAL assay to identify and eliminate endotoxin contamination from gram-negative bacteria. A commercially available assay uses horseshoe crab factor C made by recombinant DNA techniques (factor C is the key protein activated by endotoxin in the LAL assay). Rather than relying on amoebocytes collected from harvested horseshoe crabs, the recombinant protein is just as sensitive but less expensive, allows for a more standardized assay protocol, and is totally free of animal products.

Check Your Understanding

- What part of the *Escherichia coli* cell contains endotoxin? Why do gram-positive bacteria not produce endotoxins?
- Why is it necessary to test for endotoxin in water used for injectable drug preparations?

Go to **Mastering Microbiology** for videos, animations, practice tests, and more.

CHAPTER REVIEW

I • Human–Pathogen Interactions

- 25.1** If a pathogen gains access to the specific tissues it infects, disease will occur only if it first adheres to those tissues. Although adherence is required to initiate disease, it is not sufficient to initiate disease; colonization, invasion, and production of toxic substances are also required.

Q What are adhesins, and what are they typically composed of?

- 25.2** Each body region differs chemically and physically from others, and thus provides a variety of selective environments for the growth of certain microbes but not others. Colonization of tissues by a pathogenic microbe followed by growth to form populations sufficient to trigger a biological effect is necessary before disease symptoms appear.

Q Where are mucous membranes found in the body, and what do they consist of? How do they prevent pathogen invasions in the human body?

- 25.3** The pathogenicity of a pathogen is a function of its virulence, its relative ability to cause disease. Virulence is a quantitative measure that can be assayed in terms of the number of cells (or virions, if a viral pathogen) required to infect or kill 50% of a given population—the LD₅₀. Attenuated

pathogens are strains with diminished virulence and are quite useful for preparing vaccines.

Q What virulence factor, present in *Streptococcus pneumoniae* but absent from *Salmonella enterica*, makes *S. pneumoniae* so highly virulent for mice?

- 25.4** The genetics and physiology of both the pathogen and the host affect the outcome of an infectious disease. In *Salmonella* species, chromosomal islands or conjugative plasmids are present that encode several virulence factors; these mobile genetic elements can quickly spread a suite of virulence factors to other gram-negative bacteria. Susceptibility to an infectious disease is increased in a compromised host.

Q What factors might diminish the ability of a host to fight off an infectious disease?

II • Enzymes and Toxins of Pathogenesis

- 25.5** The virulence of a pathogen depends on the number and kinds of virulence factors it produces. Some pathogenic bacteria produce enzymes that function to either destroy host tissues or disarm host defenses. The activity of these enzymes releases nutrients to support growth of the pathogen and facilitate further invasiveness.

Q Give two reasons why a pathogen might benefit from the secretion of an enzyme that destroys host tissue integrity.

- 25.6** Exotoxins are toxic proteins and major virulence factors. Each exotoxin affects a specific host cell function. Enterotoxins are exotoxins that affect the small intestine. The clostridial botulinum and tetanus exotoxins are among the most poisonous substances known.

Q Assuming a person was poisoned with either botulinum toxin or tetanus toxin, how could the person's physical state signal the type of poisoning that had occurred?

- 25.7** Cytotoxins and superantigens are toxic proteins that lyse host cells and trigger a massive immune response against

host tissues, respectively. Hemolysis on a blood agar plate is a classic cytotoxic effect, whereas toxic shock syndrome, a potentially fatal condition, is one result of superantigen activity.

Q Distinguish between the mechanism of cytotoxins and AB toxins and provide one example of each.

- 25.8** Endotoxins are lipopolysaccharides derived from the outer membrane of gram-negative bacteria. Both the lipid and the polysaccharide components of endotoxin are necessary for toxicity. Symptoms of endotoxin poisoning include fever and intestinal distress.

Q Identify the structural features, origins, and major effects of endotoxins.

APPLICATION QUESTIONS

1. Coagulase is a virulence factor for *Staphylococcus aureus* that acts by causing clot formation at the site of *S. aureus* growth. Streptokinase is a virulence factor for *Streptococcus pyogenes* that acts by dissolving clots at the site of *S. pyogenes* growth. Reconcile these opposing strategies for enhancing pathogenicity.
2. Although mutants incapable of producing exotoxins are relatively easy to isolate, mutants incapable of producing endotoxins are much harder to isolate. From what you know of the structure and function of these types of toxins, explain the differences in mutant recovery.

CHAPTER GLOSSARY

Adherence the enhanced ability of a microorganism to attach to a cell or surface

Adhesins glycoproteins or lipoproteins covalently bound to the outer layer of the pathogen that function in attachment to host tissues

Attenuate to decrease or eliminate the virulence of a pathogen or virus

Bacteremia the presence of bacteria in the blood

Capsule a polysaccharide or protein outermost layer, usually rather slimy, present on some bacteria

Colonization the growth of a microorganism after it has gained access to host tissues

Dental caries tooth decay resulting from bacterial infection

Dental plaque a bacterial biofilm found on the teeth and consisting of cells embedded in a matrix of extracellular polymers and salivary products

Disease an injury to a host organism, caused by a pathogen or other factor, that

is accompanied by specific signs and symptoms that affect host function

Endotoxin the lipopolysaccharide portion of the outer membrane of most gram-negative *Bacteria*, which is a toxin when solubilized

Enterotoxin a protein that is released extracellularly by a microorganism as it grows and that produces immediate damage to the small intestine of the host

Exotoxin a protein that is released extracellularly by a microorganism as it grows and that produces immediate damage to the host

Infection an event during which a microorganism not a member of the local microbiota is established and grows in a host, regardless of whether the host is harmed

Invasion the ability of a pathogen to enter into host cells or tissues, spread, and cause disease

Mucous membrane a layer of mucus-covered epithelial cells in the body that communicates with the external environment

Mucus a viscous liquid composed of mucin secreted by specialized epithelial cells that contains water-soluble glycoproteins and proteins that retain moisture and aid in resistance to microbial invasion on mucosal surfaces

Opportunistic pathogen an organism that causes disease only in the absence of normal host resistance

Pathogen a disease-causing microorganism

Pathogenicity the ability of a pathogen to cause disease

Septicemia a bloodborne systemic infection

Toxicity the ability of an organism to cause disease by means of a preformed toxin that inhibits host cell function or kills host cells

Virulence the relative ability of a pathogen to cause disease

Virulence factors substances or strategies of a pathogen that indirectly or directly enhance invasiveness and host damage by facilitating and promoting infection

Periodontal Disease and Alzheimer's: Evidence for Causation?

Alzheimer's disease (AD) is characterized by the presence of insoluble aggregates of amyloid- β protein ($A\beta$) in the brain, producing plaques that interfere with cognitive brain function. Although $A\beta$ has traditionally been viewed as an injurious substance, studies have now shown that it may function as an innate antimicrobial defense to protect the brain from bacteria that cross the blood-brain barrier. In such cases, the invading cells become entombed in a meshwork of $A\beta$, minimizing their growth and dissemination in the brain (see Figure 26.3). Chronic or heavy bacterial infections are believed to initiate the $A\beta$ plaques that lead to Alzheimer's symptoms, and a recent report has implicated a specific bacterium in the development of these plaques: *Porphyromonas gingivalis*, the causative agent of periodontal disease.

It has long been recognized that Alzheimer's patients also often suffer from chronic gum disease, including gingivitis and periodontitis, and multiple reports are emerging that suggest the onset of gum disease is a risk factor that precipitates AD. In one study, researchers introduced oral *P. gingivalis* infection in mice and subsequently documented *P. gingivalis*

colonization of the brain. There, the invading bacteria produced neurotoxic proteases called gingipains (red, on cells of *P. gingivalis*, top left photo). This triggered inflammation and accumulation of $A\beta$ (green, on cells, top right photo), which colocalized with the gingipains on cells of *P. gingivalis* (bottom photo), ultimately promoting $A\beta$ plaque formation. However, when gingipain inhibitors were administered, bacterial numbers diminished, inflammation and production of $A\beta$ subsided, and neurons in the hippocampus were restored, suggesting that such inhibitors may reduce $A\beta$ plaque formation and serve as a new weapon against AD.

Although the study is not conclusive, the results indicate that *P. gingivalis* infection may be a contributing factor in the development of AD. Further study along these lines may eventually yield a more complete understanding of AD pathology, as well as more effective treatment options.

We began this unit by considering the associations of microbes with humans, and in the last chapter we discussed pathogenicity, virulence, and risk factors for infection. In this and the next chapter, we focus on mechanisms used by vertebrates to resist pathogens and the diseases they cause, the science of *immunology*. In this chapter, we present concepts of **innate immunity**, inborn host defenses against a *broad range* of pathogens. In Chapter 27 we discuss **adaptive immunity**, the essential second tier of the immune system that targets *specific* pathogens to minimize their harmful effects.

I • Fundamentals of Host Defense

The human body has both innate (broadly targeted) and acquired (highly specific) immune mechanisms to either prevent or respond to invasion by pathogens. This highly developed “search and destroy” system maintains human health from potentially harmful microbes in the environment.

We begin with an overview of innate and adaptive immunity and follow this with a consideration of the human body’s significant natural barriers to invasion by pathogens.

26.1 Basic Properties of the Immune System

Immunity is the ability of an organism to resist infection. The human immune system employs a two-pronged defense against invading pathogens. *Innate immunity*, the first of these interconnected defensive mechanisms, is the built-in capacity of the immune system of multicellular organisms to target pathogens that are seeking to colonize the host. Depending on the virulence of the pathogen, the infectious dose, and the immune competence of the individual, innate mechanisms alone may be insufficient to eliminate the pathogen. In such cases, and assuming that the pathogen has not quickly killed the host, *adaptive immunity* is triggered within the individual against those specific pathogens that have overcome the innate defenses. Each adaptive immune response is specifically targeted to a particular invading pathogen, such as a single strain of virus. **Figure 26.1** compares and contrasts the fundamental elements of each of these indispensable branches of the immune system.

Principles of Innate Immunity

Innate immunity is a noninducible, preexisting ability of the body to recognize and destroy a broad range of pathogens or their products. Innate immune responses develop quickly, typically within

immune
response

Figure 26.1 Overview of the two-pronged immune response. Principal characteristics of innate (shown in purple) and adaptive (shown in orange) immunity. Phagocytes and lymphocytes are the primary effector cells of innate and adaptive immunity, respectively, but note that not all immune cells are shown (compare to Figure 26.5).

several hours of exposure to a pathogen or its product, and they do not require previous exposure to a pathogen or its products for activation. Eukaryotes have functionally similar pathogen recognition mechanisms that lead to rapid and effective host defense. For example, pathogen recognition in the insect *Drosophila* (fruit fly) is carried out in much the same way as it is in humans, using immune cells that show structural and evolutionary homology.

In addition to a variety of physical and chemical barriers to infection that we will describe in Section 26.2, innate immunity is largely dependent on the activity of **phagocytes** (Figure 26.1), cells that ingest, kill, and digest microbial pathogens. Phagocytes include **neutrophils**, **macrophages**, **dendritic cells**, and **eosinophils**, and we define their distinctive features in Section 26.4. In addition to phagocytes, cells of the innate immune system consist of **mast cells** and **basophils**, both of which trigger inflammation when activated (Section 26.8), and **natural killer (NK) cells**, which identify and destroy host cells that have become compromised and are therefore dangerous to the host, such as cells that are infected by a pathogen or are cancerous (Section 26.10).

infection in the
human body

Principles of Adaptive Immunity

When innate immune responses fail to eliminate an invading pathogen, adaptive immunity is activated. Adaptive immunity is the *acquired* ability to recognize and destroy a specific pathogen or its products. Adaptive responses show **specificity** because they are directed at unique pathogen components or products called **antigens**, which often define a particular strain of pathogen or type of foreign material. Macrophages and dendritic cells ingest and process pathogens to present peptide antigens to **T lymphocytes (T cells)**, which play a key role in initiating the adaptive response. Another adaptive immune cell, the **B lymphocyte (B cell)**, also presents antigen to T cells. The presented antigen peptides, called **epitopes**, bind specific receptors on the lymphocyte surface, triggering the expression of genes that cause the lymphocytes to proliferate and differentiate. Differentiated B cells called **plasma cells** specialize in the production of antigen-specific proteins called **antibodies (immunoglobulins)**, which bind the pathogen and mark it for destruction.

Unlike the comparatively rapid innate response, a protective adaptive response usually takes several days to develop, and the strength of the adaptive response increases as the numbers of antigen-reactive lymphocytes increase. Although adaptive immune responses are typically slower than innate response mechanisms, they are highly specific and result in **immune memory**, the ability of lymphocytes to quickly respond after subsequent exposure to a previously encountered antigen.

With this broad overview of inborn and acquired immune responses in place, we now consider the many natural barriers to infection that exist in the healthy human body. It is only after one or more of these barriers has been breached that pathogen invasion can occur and the immune system is brought into play.

Check Your Understanding

- What major class of immune cells mediates an innate immune response? What additional type of immune cells is required for an adaptive immune response?
- What term is used to describe the unique molecules found on the surface of different pathogens?

26.2 Barriers to Pathogen Invasion

Although the vast majority of microorganisms that associate with the human body are not pathogenic, certainly some do cause disease. The best defense against infectious diseases for the human body is to prevent pathogens from colonizing in the first place. Humans have a host of resistance factors that inhibit pathogen colonization and thereby prevent the onset of infectious diseases. These include a variety of physical and chemical barriers to microbial infection. In addition, the condition of the host and the composition of microorganisms that normally inhabit the host are factors that are often the tipping point between health and disease.

Natural Host Resistance

Several resistance factors common to vertebrate hosts inhibit infection by most pathogens in a nonspecific way (Figure 26.2). For example, the presence of normal microbiota in the human body is critically important for resisting pathogen infection, especially on the skin and in the mucosal tissues of the gastrointestinal, respiratory, and reproductive tracts (Chapter 24). Pathogens do not easily infect tissues on which normal microbiota are well established because the harmless microbes limit available nutrients and sites for

Figure 26.2 Barriers to infection in the human body. These barriers provide natural resistance to colonization and infection by pathogens.

infection by the pathogens. Although the *competitive exclusion* of invading pathogens by resident microbes is technically not a component of the host’s immune system, the nonpathogenic normal microbiota found in or on the body play a major role in preventing disease through this principle. It is not uncommon for disruptions to the composition of the normal microbiota, such as that which may occur when antibiotic drug treatments nonspecifically kill harmless and even beneficial microbes in the body, to trigger the onset of disease by opportunistic pathogens.

The ability of a particular pathogen to cause disease in a host is highly variable. For instance, certain animal species, including raccoons and skunks, are much more susceptible to the rabies virus than are others, such as the opossum, which only rarely develops the disease. Anthrax infects many species of animals, causing disease symptoms varying from fatal blood poisoning in cattle to the mild pustules of human cutaneous anthrax. Introduction of the same pathogen by other routes, however, may challenge the resistance of the host. For example, anthrax causes a localized infection when acquired through the skin but a lethal, systemic infection when acquired through the mucous membranes of the lungs (► Sections 30.9 and 32.8). Another barrier to infection is the fact that diseases of endothermic (“warm-blooded”) animals, such as birds and mammals, are rarely transmitted to ectothermic (“cold-blooded”) animals, such as amphibians and reptiles, and vice versa. Presumably, the anatomical and physiological features of one group are not compatible with pathogens that infect the other group.

In addition to these factors, the general condition of the host plays a role in the balance between health and disease. Susceptibility to infections is higher in the very young and the very old, as well as those suffering from nutritional or stress-related problems. For example, the intestinal microbiota matures over time and thus infants under one year of age often contract diarrhea caused by bacterial or viral pathogens more readily than do adults. Conversely, the immune system of older adults may be weakened or compromised from medical procedures or drug therapy, leading to a higher susceptibility to infectious disease. Other problems that affect both the young and the old—smoking, poor diet, intravenous drug use, excessive alcohol consumption, chronic lack of sleep—can all play a role in whether a pathogen can infect a host and cause disease.

Infection Site and Tissue Specificity

Most pathogens must adhere to and colonize the site of exposure to initiate infection. Even if pathogens adhere to an exposure site, the organisms cannot colonize the host if the site is not compatible with the pathogen’s nutritional and metabolic needs. For example, if cells of *Clostridium tetani* (cause of the disease tetanus) were ingested, tetanus would not normally result because the pathogen would be either killed by the acidity of the stomach or unable to compete with the well-developed normal intestinal microbiota. If, on the other hand, *C. tetani* cells or endospores were introduced into a puncture wound, the organism would grow and produce tetanus toxin in the anoxic zones created by local tissue death. Conversely, enteric bacteria, such as *Salmonella* and *Shigella*, do not normally cause wound infections but can infect the intestinal tract and cause gastrointestinal illness.

In some cases, pathogens interact exclusively with members of a few closely related host species because the hosts share tissue-specific receptors, important in establishing infection (◀ Section 25.1). For

TABLE 26.1 Tissue specificity in infectious disease

Disease	Tissue or cell type infected	Pathogen
Acquired immunodeficiency syndrome (AIDS)	T-helper lymphocytes	Human immunodeficiency virus (HIV)
Botulism	Motor end plate	<i>Clostridium botulinum</i>
Cholera	Small intestine epithelium	<i>Vibrio cholerae</i>
Dental caries	Oral epithelium	<i>Streptococcus mutans</i> , <i>S. sobrinus</i> , <i>S. mitis</i>
Diphtheria	Throat epithelium	<i>Corynebacterium diphtheriae</i>
Gonorrhea	Mucosal epithelium	<i>Neisseria gonorrhoeae</i>
Influenza	Respiratory epithelium	Influenza A and influenza B viruses
Malaria	Blood (erythrocytes)	<i>Plasmodium</i> spp.
Pyelonephritis	Kidney medulla	<i>Proteus</i> spp.
Spontaneous abortion (cattle)	Placenta	<i>Brucella abortus</i>
Tetanus	Inhibitory interneuron	<i>Clostridium tetani</i>

example, human immunodeficiency virus (HIV, the causative agent of AIDS) infects only humans and their closest primate relatives, including the great apes. This is because the HIV-binding cell surface proteins CXCR4, present on human T lymphocytes, and CCR5, present on human macrophages (Section 26.1), are also expressed in great apes. Other animals, including most other primates, lack CXCR4 and CCR5 and are therefore not susceptible to HIV infection. Many other pathogens exhibit tissue specificity to such a degree that they infect only a single species. For example, a rhinovirus that infects nasal epithelial cells in humans, causing symptoms of the common cold, would generally not infect and cause similar symptoms in a nonhuman host. Table 26.1 presents some other examples of tissue specificity in pathogens.

Physical and Chemical Barriers to Infection

The structural integrity of tissue surfaces poses a barrier to penetration by microorganisms (◀ Section 25.2). The tight junctions between epithelial cells that line body tissues inhibit invasion and infection (Figure 26.2). In the skin and mucosal tissues, potential pathogens must first adhere to tissue surfaces and then grow at these sites before traveling elsewhere in the body. Mucosal surfaces are coated with a layer of protective mucus that traps microorganisms, pollen, and other foreign agents. Epithelial cells underlying the mucus layer have cilia on their surfaces that carry out coordinated movements to expel suspended pathogens and keep them from adhering to tissues. This combination of mucus and ciliary motion plays a key role in removing inhaled microorganisms from the mucosal surfaces of the trachea and bronchial tubes, thus preventing microbial colonization of the lungs.

In the central nervous system (CNS), pathogens that are able to penetrate the blood–brain barrier present a special challenge

(a)

(b)

Figure 26.3 Amyloid- β ($A\beta$) protein as an innate defense in the central nervous system. (a) Bacteria that breach the blood–brain barrier stimulate production of $A\beta$ protein, which forms a dense network of fibrils to trap the pathogens and minimize their invasiveness. (b) Fluorescence micrograph of cells of *Salmonella* bacteria (green) immobilized by a mesh of $A\beta$ fibrils (red), enabling more efficient pathogen destruction by immune mechanisms.

because adaptive immune responses mediated by lymphocytes are less effective at these sites. However, a long-misunderstood protein—amyloid- β ($A\beta$)—may play a role in innate defense of the brain by containing invading pathogens. As discussed in MicrobiologyNow at the beginning of the chapter and shown in **Figure 26.3**, $A\beta$ proteins form a mesh of fibrils to trap bacteria that are able to invade the CNS. However, in cases of heavy or chronic infection, excessive deposition of $A\beta$ may cause the fibrils to aggregate into dense, insoluble complexes that form amyloid plaques in the brain tissue, one of the hallmarks of Alzheimer’s disease.

Sebaceous glands in the skin secrete fatty acids and lactic acid, lowering the acidity of the skin to pH 5 and inhibiting colonization by many pathogenic bacteria (blood and most internal organs are about pH 7.4). Potential pathogens ingested in food or water must survive the strong acidity (pH 2) and digestive enzymes, such as pepsin, in the stomach (Figure 26.2). Although the pH returns to neutral in the lower intestinal tract, pathogens that survive passage through the stomach must then compete with the abundant resident microbiota present in the small and large intestines (◀ Figure 24.3). In addition to the established normal microbiota that exist at many potential infection sites, resistance to infection and invasion is enhanced by antibacterial substances called *defensins*, produced in the skin, lungs, and gut. Finally, the lumen of the kidney, the eye, the respiratory system, and the cervical mucosa are constantly

bathed with tears, mucus, or other secretions that contain *lysozyme*, an enzyme that can kill bacteria by digesting the cell wall.

The human body is thus naturally protected by a host of physical barriers, chemicals, and secretions, all of which combine to naturally suppress pathogen invasion and infection. However, breaching of these defenses by a pathogen activates cellular defenses of the immune system, beginning with mechanisms of microbe recognition and innate responses. We now consider the organs and cellular components of the immune system before exploring how this complex and interrelated system works.

Check Your Understanding

- How do pathogens recognize the tissues they infect?
- Identify physical and chemical barriers to pathogens. How might these barriers be compromised?
- What other factors may control the outcome of an infectious disease?

II • Cells and Organs of the Immune System

Cellular components of the immune system are derived from **hematopoietic stem cells in the bone marrow. These cells circulate throughout the body in the blood and lymph systems in constant surveillance for foreign cells, viruses, or their antigenic products.**

The immune response is a result of the activities of a wide variety of specialized cells that circulate throughout the body, primarily through the blood and *lymph*, a fluid similar to blood but which lacks red blood cells.

26.3 The Blood and Lymphatic Systems

Circulatory systems in the human body include separate vasculature for blood and lymph. It is through circulation of these fluids that cells and proteins of the immune system are transported to the various tissues and organs of the body. All cells found in the blood and lymph are derived from **hematopoietic stem cells** found primarily in the bone marrow but also in the gut. Hematopoietic stem cells continuously divide and differentiate to supply the body with both erythrocytes (red blood cells) and **leukocytes** (white blood cells).

Blood and Lymph Circulation

Blood is pumped by the heart through arteries and capillaries throughout the body and is returned to the heart through the veins (**Figure 26.4a, b**). In the capillary beds, leukocytes and solutes pass to and from the blood into the lymphatic system. Lymph drains from extravascular tissues into lymphatic vessels (lymph capillaries and lymph ducts) and then into **lymph nodes** throughout the lymphatic system (Figure 26.4b–d). Lymph nodes contain leukocytes arranged to encounter antigens, such as those found on microorganisms, as they travel through the lymphatic circulation. Lymph containing antibodies and immune cells empties into the blood circulatory system via the thoracic lymph duct (Figure 26.4a).

Figure 26.4 The blood and lymphatic systems.

(a) Blood and lymph circulation in the body. Major blood vessels and associated organs are shown in red. Major lymphatic organs and vessels are shown in green. The primary lymphoid organs are the bone marrow and thymus. The secondary lymphoid organs are the lymph nodes, spleen, and mucosa-associated lymphoid tissue (MALT). (b) Connections between the

lymphatic and blood systems. Blood flows from the veins to the heart, to the lungs, and then through the arteries to capillaries in tissues. Exchange of solutes and cells occurs between blood and lymphatic capillaries. Lymph drains from the thoracic duct into the left subclavian vein of the blood circulatory system. (c) The exchange of cells between the blood and lymphatic

capillaries are closed vessels, but cells pass from blood capillaries to lymphatic capillaries and back by the process of diapedesis. (d) A secondary lymphoid organ, the lymph node, showing the major anatomical areas and the immune cells concentrated in each area. The anatomy of the MALT and the spleen is analogous to that of the lymph nodes. APCs, antigen-presenting cells.

Mucosa-associated lymphoid tissue (MALT) is another organized lymphoid tissue containing leukocytes that interact with antigens that enter the body through mucous membranes, including those of the gut, the genitourinary tract, and the respiratory tract.

The *spleen* is an important organ in immunity and consists of *red pulp*—rich in red blood cells and macrophages—and *white pulp*, which consists of organized lymphocytes and phagocytes arranged to filter blood in a manner similar to lymph nodes and MALT. Collectively, the lymph nodes, MALT, and spleen are called **secondary lymphoid organs** (or tissues, in the case of MALT, Figure 26.4). The

secondary lymphoid organs are the sites where antigens interact with antigen-presenting cells (Section 26.4) and lymphocytes to trigger the adaptive immune response.

Hematopoiesis

Hematopoietic stem cells are precursor cells found in bone marrow and the gut that can differentiate into any type of blood cell (see Figure 26.5), a process called **hematopoiesis**. Stem cell differentiation in these tissues is influenced by soluble **cytokines** and **chemokines**,

TABLE 26.2 Major cell types found in normal human blood	
Cell type	Cells per milliliter
Erythrocytes	$4.2\text{--}6.2 \times 10^9$
Leukocytes ^a	$4.5\text{--}11 \times 10^6$
Lymphocytes	$1.0\text{--}4.8 \times 10^6$
Granulocytes and monocytes	Up to 7.0×10^6

(d) Monocyte

^aLeukocytes include all nucleated blood cells (Figure 26.5).

proteins that direct immune cell production, function, and movement, thereby modulating the immune response (Section 26.5). Following differentiation, newly formed blood cells enter the circulation and reach other parts of the body, where the leukocytes further mature and become activated upon antigen encounter.

Blood consists of cellular and noncellular components, including many cells and molecules active in the immune response (Table 26.2). The most numerous cells in human blood are *erythrocytes*, small, nonnucleated cells that carry oxygen from the lungs to the tissues. About 0.1% of the cells in blood, however, are white blood cells—leukocytes—of which there are many different types (Table 26.2). Blood cells are suspended in **plasma**, a liquid that contains proteins and other solutes. Outside the body, blood or plasma quickly forms an insoluble fibrin clot, remaining liquid only when an anticoagulant such as potassium citrate or heparin is added. When blood clots, the insoluble proteins trap the cells in a large, insoluble mass. The remaining fluid, called **serum**, lacks both cells and clotting proteins. Serum does, however, contain a high concentration of other proteins, in particular antibodies, key players in the adaptive immune response, as we will learn in Chapter 27.

Check Your Understanding

- Describe the circulation of a leukocyte from the blood to the lymph and back to the blood.
- What soluble molecules determine whether a particular hematopoietic stem cell will become a phagocyte, lymphocyte, or erythrocyte?

26.4 Leukocyte Production and Diversity

The innate and adaptive immune responses are mediated by several types of leukocytes (Table 26.2). From its hematopoietic stem cell precursor, a leukocyte will differentiate and mature through either the *myeloid* or the *lymphoid* lineage (Figure 26.5). Leukocytes move throughout the body and, through a process called *diapedesis* (also called *extravasation*), pass from blood to interstitial spaces. Leukocytes may then be collected with lymph into lymphatic vessels, where they are eventually returned to the blood circulatory system (Figure 26.4c).

Myeloid Cells—Monocytes and Granulocytes

Myeloid cells, the principal effector cells of innate immunity, are derived from myeloid precursor cells. Mature myeloid cells develop from one of two lineages: **monocytes** or **granulocytes** (Figure 26.5 and Table 26.2). Immature monocyte precursor cells circulate in the blood for several days before moving into other tissues and differentiating into *macrophages* or *dendritic cells*. These phagocytic cells function as **antigen-presenting cells (APCs)** because they use a special type of cell surface protein called a class II **major histocompatibility complex (MHC)** to present engulfed and processed antigens to T lymphocytes, which then initiate an adaptive immune response (Figure 26.5). We will revisit MHC proteins later in this chapter and discuss them in detail in Chapter 27.

Macrophages are often the first defensive cells that interact with a pathogen and are abundant in many tissues and organs, especially the spleen, lymph nodes, and MALT, where they constitute up to 15% of total cells. Because they ingest and destroy most pathogens and foreign molecules that invade the body, macrophages are essential to the innate response. Dendritic cells are found throughout the body tissues and are especially abundant along epithelial linings, including the skin and mucous membranes. When dendritic cells ingest antigen, they migrate to nearby lymph nodes (Figure 26.4), where they are extremely efficient at presenting antigen to T lymphocytes. Thus, dendritic cells are an important link between innate and adaptive immunity. The specialized antigen-presenting properties of macrophages and dendritic cells will be examined in Section 27.5.

Granulocytes are the second lineage of cells derived from myeloid precursors. Granulocytes contain cytoplasmic inclusions, or granules, that are visible in stained microscopic preparations. These granules contain toxins or enzymes that are released to destroy target cells. One granulocyte, the *neutrophil*, also called a *polymorphonuclear leukocyte (PMN)*, is an abundant, highly motile phagocyte that responds rapidly to pathogen challenge, an activity that is central to innate immunity. Neutrophils are found predominantly in the bloodstream and bone marrow, from where they migrate to sites of active infection. *Eosinophils* are a second, much less numerous, type of phagocytic granulocyte. A major function of eosinophils is to destroy larger, extracellular parasites, such as infectious helminths (worms, ► Section 34.7), by secreting cytotoxic enzymes and then clearing the debris from the body tissues.

Other granulocytes include *basophils*, which circulate in the blood, and *mast cells*, which reside in host tissues (Figure 26.5). The intracytoplasmic granules of these cells contain histamine and other mediators that function to initiate an inflammatory response when secreted, a process called *degranulation*. Mast cell and basophil degranulation is responsible for certain types of allergic reactions (► Section 28.1).

Figure 26.5 Lineage and diversity of immune response cells. Immune cells develop from hematopoietic stem cells in the bone marrow into either myeloid precursors or lymphoid precursors. These precursors, in turn, differentiate into mature cells that have various immune functions. (Erythrocytes also develop from myeloid precursors.)

Lymphocytes

Lymphocytes are specialized leukocytes derived from lymphoid precursor cells (Figure 26.5 and Table 26.2). As we have discussed (Section 26.1), there are two major types of lymphocytes: *B cells* (B lymphocytes) and *T cells* (T lymphocytes) (Figure 26.5). Whereas B cells originate and mature in the bone marrow, T cells begin their development in the bone marrow but migrate to the *thymus* to mature (Figure 26.4a and see Figure 27.2). In mammals, the bone marrow and thymus are called **primary lymphoid organs** because they are the sites where lymphoid stem cells differentiate into functional, antigen-specific lymphocytes (Figure 26.4a). Naïve B and T cells circulate through the blood and lymph system and into the *secondary lymphoid organs* (Section 26.3) where, upon antigen encounter, they become activated and further differentiate into effector and memory cells.

B cell surfaces are covered with **B cell receptors (BCRs)**, membrane-bound immunoglobulins that function to bind free

antigen. Following internalization and processing of bound antigen, B cells—like dendritic cells and macrophages—function as specialized APCs, employing class II MHCs to present antigen to T lymphocytes (see Figure 27.6). The T cells, in turn, interact with presented antigens through membrane-bound **T cell receptors (TCRs)**, protein complexes that specifically bind antigens presented on MHCs. We explore the roles of B and T lymphocytes in the adaptive immune response in Chapter 27.

Like B and T cells, natural killer (NK) cells (Figure 26.5) are derived from lymphoid precursors. However, unlike B and T lymphocytes, NK cells function primarily in innate immunity. NK cells rid the body of virus-infected and tumor cells using a mechanism that distinguishes healthy versus compromised cells based on the presence (or absence) of specific surface molecules (Section 26.10).

Check Your Understanding

- How does the development of B, T, and NK cells differ from that of dendritic cells and macrophages?
- Distinguish between the primary lymphoid organs and the secondary lymphoid organs. What is the relationship between the components of these two groups?

III • Phagocyte Response Mechanisms

Phagocytes respond quickly to tissue damage and microbial invasion, whereupon they recognize, engulf, and digest pathogens through various molecular mechanisms. Phagocytic activities are the hallmark of the innate immune response.

Innate immunity is primarily driven by the activities of phagocytes (Section 26.1). These cells recognize common structural features found on and in pathogens. Interactions with pathogens activate genes in the phagocytes that control the transcription, translation, and expression of proteins that eventually lead to the destruction of the pathogens.

Innate immunity responds within minutes of a phagocyte engaging a pathogen, but it is not always effective in controlling infections. To counter these infections, certain phagocytes also activate adaptive immunity by processing and presenting antigens to receptors on T lymphocytes (Chapter 27). However, because an adaptive response to a specific pathogen takes several days to develop, the ability of phagocytes to quickly respond to microbial invasion is an indispensable mechanism for infection containment.

26.5 Pathogen Challenge and Phagocyte Recruitment

When a pathogen breaches the physical and chemical barriers of a host (Figure 26.2) and causes an infection, the immune system is mobilized to protect the host from further damage. Innate immunity is the first line of defense and is critical for host protection for about four days after an infection begins. Phagocytes engulf and destroy pathogens, often initiating complex host-mediated inflammatory reactions when they do (Section 26.8).

Microbial Invasion

The initial inoculum of a pathogen is usually insufficient to cause host damage, even if a pathogen gains access to tissues. For the pathogen to be successful, it must attach, multiply, and colonize the tissue (◀ Figure 25.1), and these events require that the pathogen find appropriate nutrients and environmental conditions for growth.

Following colonization, a pathogen must usually invade tissues to initiate disease. **Invasion** is the ability of a pathogen to enter into host cells or tissues, multiply, spread, and cause disease. Microbial infections often begin at breaks or wounds in the skin (Figure 26.6a) or on the mucous membranes of the respiratory, digestive, or genitourinary tract, surfaces that are normally microbial barriers (Figure 26.2). In some cases, growth may also begin on intact mucosal surfaces, especially if the composition of the normal microbiota has been altered or

Figure 26.6 Microbial invasion and the innate immune response. (a) Tissue damage, such as that caused by a tack puncturing the skin, can lead to invasion by microorganisms and the release of cytokines and chemokines from damaged host cells. (b) Phagocytes, especially neutrophils, are recruited to the site of infection by the cytokine–chemokine gradient, squeezing out of dilated capillaries via diapedesis. (c) Invading microorganisms are cleared by phagocytosis, and the tissue is restored to health. See Figures 26.1 and 26.5 for functional descriptions of some of the cells and components shown here, and see Table 26.1 for photomicrographs and quantitative data on some of the cells shown here.

eliminated, for example by antibiotic therapy. Tissue damage caused by invasive pathogens or injury triggers the recruitment of large numbers of phagocytes and other immune cells to the site of infection.

Tissue Damage and Chemokine Release

When microorganisms invade and damage host tissues, resident phagocytes (usually tissue macrophages) engage the microbes and become activated. The activated macrophages and damaged host cells release *cytokines* and *chemokines* into the surrounding tissues (Figure 26.6a). Cytokines bind specific receptors on cells and induce a particular response from them, usually by activating a signaling pathway that controls transcription and protein synthesis. Chemokines are an important subclass of cytokines that have the specific role of recruiting circulating immune cells, especially neutrophils (Figure 26.5), to the site of injury.

Resident macrophages, which are found in all of the body's organ systems, are stimulated by the presence of invading pathogens to secrete chemokines that establish a gradient of *chemoattractants*. These molecules bind receptors on other immune cells, especially neutrophils and T cells, and recruit them to the site of infection (Figure 26.6b). This triggers a neutrophil-mediated inflammatory response and, later, an adaptive immune response facilitated by lymphocytes against the specific invading agent or its toxic products.

Localized inflammation allows neutrophils, the most numerous circulating phagocytes, to migrate quickly along the chemotactic gradient to the site of infection (Figure 26.6b). Once there, chemokine-mediated binding reactions promote neutrophil adhesion to the inner wall of the blood capillary, a process called *margination*. The halted neutrophils then undergo *diapedesis*, the movement of leukocytes from the bloodstream to surrounding infected tissues by squeezing between endothelial cells lining the capillaries (Figure 26.6b). Higher than normal numbers of neutrophils in the blood or at a site of inflammation indicate an active response to a current infection.

Neutrophils and other phagocytes that encounter pathogens in damaged areas must be able to recognize, capture, and destroy pathogens to clear infections and restore body tissues to a healthy state (Figure 26.6c). We explore the molecular mechanisms that facilitate these cellular interactions in the next section.

Check Your Understanding

- Describe the mechanisms by which circulating phagocytic cells are recruited to a site of infection.

26.6 Pathogen Recognition and Phagocyte Signal Transduction

The first type of immune cell to be activated in the innate response is typically a phagocyte, whose primary function is to engulf and destroy pathogens. Phagocytes include neutrophils, eosinophils, and monocytes, which are found primarily in the blood, and macrophages and dendritic cells, which occur primarily in the body tissues (Figure 26.5). But how do these cells distinguish pathogens and other foreign agents from the myriad other cells in the body?

(a)

(b)

Figure 26.7 Pathogen recognition by phagocytes. (a) Phagocytes interact with pathogens by way of preformed pattern recognition receptors (PRRs) that bind to pathogen-associated molecular patterns (PAMPs). Binding of a PAMP by a phagocyte PRR stimulates the phagocyte to destroy the pathogen and activate other phagocytes. (b) Colorized scanning electron micrograph of a neutrophil (blue) phagocytosing several cells of methicillin-resistant *Staphylococcus aureus* (MRSA; magenta). For more on MRSA, see Explore the Microbial World in Chapter 29 and Section 31.9.

Moreover, once invaders are recognized, how do phagocytes capture and destroy them? We address these topics now.

Pathogen-Associated Molecular Patterns

The macromolecules inside and on the surface of pathogens contain **pathogen-associated molecular patterns (PAMPs)**, repeating

structural subunits common to broadly related groups of infectious agents. PAMPs may include polysaccharides, proteins, nucleic acids, or even lipids. For example, a common PAMP is the lipopolysaccharide (LPS) common to all gram-negative bacterial outer membranes (◀ Section 2.4). Other PAMPs include bacterial flagellin, the double-stranded RNA (dsRNA) of certain viruses, and the lipoteichoic acids of gram-positive bacteria (◀ Section 2.3). Like all PAMPs, these molecules are found on various pathogens but are absent from host cells. Therefore, PAMPs serve as markers by which phagocytes can identify microbes, even if the pathogens have not been encountered previously.

Pattern Recognition Receptors

Phagocytes employ a pathogen-recognition system that triggers a timely and appropriate response, leading to recognition, containment, and destruction of pathogens. Phagocytes produce soluble or membrane-bound proteins called **pattern recognition receptors (PRRs)** that recognize and bind PAMPs, allowing phagocytes to interact quickly and effectively with pathogens (Figure 26.7a). The interaction of a PAMP with a PRR activates the phagocyte to ingest and destroy the targeted pathogen by phagocytosis (Figure 26.7b and Section 26.7).

PRRs were first observed in phagocytes of *Drosophila*, the fruit fly, where they are called *Toll receptors*, and they have since been

identified as important components of microbial recognition throughout the animal kingdom (see Explore the Microbial World, “Pattern Recognition Receptors of Hydrothermal Vent Tube Worms Facilitate Endosymbiosis”). Structural, functional, and evolutionary homologs of the Toll receptors, called **Toll-like receptors (TLRs)**, are widely expressed on mammalian innate immune cells. TLRs are found associated with membranes on the surface of or in intracellular vesicles of all types of phagocytes. At least nine TLRs in humans interact with a variety of cell surface and soluble PAMPs from viruses, bacteria, and fungi (Table 26.3).

Each TLR on a human phagocyte recognizes and interacts with a specific PAMP. For example, TLR-2, a PRR on human phagocytes, interacts with peptidoglycan, a PAMP present in the cell wall of nearly all bacteria (Figure 26.8). This PAMP–PRR interaction activates the phagocytes, which then target gram-positive pathogens with exposed peptidoglycan. Access to the peptidoglycan of gram-negative bacterial cell walls is blocked by the surface lipopolysaccharides. However, another PRR found on phagocytes, TLR-4, interacts with the LPS of gram-negative bacteria, such as *Salmonella* spp., *Escherichia coli*, and *Shigella* spp. (Table 26.3 and see Figure 26.9).

Several soluble host molecules function similarly to these phagocyte-associated PRRs. The *NOD-like receptors (NLRs)* are a family of soluble PRRs found in the cytoplasm that have a nucleotide-binding domain (NOD). NOD1 and NOD2 interact with

Pattern Recognition Receptors of Hydrothermal Vent Tube Worms Facilitate Endosymbiosis

Invertebrates and plants lack adaptive immunity but have a well-developed innate immune response to a wide variety of pathogens. As discussed in Section 26.6, virtually all multicellular organisms respond to pathogen invasion by recognizing signature molecules found on pathogen surfaces. These molecules contain conserved, repetitive structures called pathogen-associated molecular patterns (PAMPs) that include molecules such as the lipopolysaccharide (LPS) and flagellin of gram-negative bacteria, the peptidoglycan of gram-positive bacteria, and the

mutualistic partnership rather than a confrontation between a host and the bacteria that colonize it. As we learned in Chapter 23, a wide variety of plants and animals maintain symbiotic relationships with microorganisms. There we discussed the association of tube worms that develop near hydrothermal vents in the deep sea with autotrophic, sulfur-oxidizing bacteria (SOB) that inhabit their *trophosome*, a spongy internal organ that comprises most of the volume of the 1- to 2-m-long worms (**Figure 1**). These SOB form an endosymbiosis with the worms in which the bacteria provide all organic carbon requirements for their animal host in exchange for a steady supply of essential metabolites, in particular H_2S , O_2 , and CO_2 . H_2S is the energy source for the SOB; they oxidize it to S^0 and then SO_4^{2-} and respire the electrons to generate a proton motive force that drives ATP synthesis. Oxygen (O_2) is required as a terminal acceptor of electrons that have traversed the electron transport chain. CO_2 is the carbon source and is incorporated into bacterial cell material by way of

the Calvin cycle, the major means of autotrophy in chemolithotrophic bacteria.

This fascinating association raises the question of how it is established. Specifically, how does the tube worm populate its trophosome with SOB to the exclusion of other, potentially pathogenic, bacteria? The answer appears to be closely linked to MAMPs associated with the endosymbiotic SOB. Although host PRRs are typically used to recognize and eliminate pathogens, the study of tube worms and other animals that harbor endosymbiotic microbes shows a broader functionality for PRRs in that they can also interact beneficially with MAMPs to selectively populate a host with nonpathogenic symbionts.

The tube worm trophosome contains a large number of specialized host immune cells called *bacteriocytes*, and it is within these cells that the bacterial symbionts take up residence. The tube-worm bacteriocytes express high levels of PRRs that recognize MAMPs, such as specific cell surface lipoproteins associated with SOB. This positive interaction locates the bacteria to the trophosome and, with a steady supply of

simple nutrients from the hydrothermal vent system delivered by blood circulating in the worm, stimulates colonization and growth of the symbionts in their animal host.

As this example illustrates, in addition to providing a rapid response to pathogen challenge, innate immune mechanisms—specifically, the interaction of PRRs with MAMPs—may also serve the primary role in governing host-symbiont interactions and the establishment of endosymbiotic relationships.

Given the critical role innate immune mechanisms play in maintaining the animal-bacterial symbiosis within the tube-worm trophosome, it is likely that similar tightly choreographed molecular mechanisms constitute a host-microbe “dialogue” that helps to maintain balanced communities of beneficial microbiota in virtually all animals, including humans.

double-stranded RNA of certain viruses. The term *microbe-associated molecular pattern*, or MAMP, is also commonly used to describe signature molecules found on microorganisms. However, “MAMP” is a broader term than “PAMP” because it includes components found on microorganisms that are not pathogenic.

Unlike PAMPs, which are exploited specifically for innate defense against pathogens, MAMPs found on nonpathogenic bacteria can serve an entirely different purpose—that of facilitating, through host pattern recognition receptors (PRRs), a

Figure 1 Hydrothermal vent tube worms harboring endosymbiotic sulfur-oxidizing bacteria. Figure 26.8 A Toll-like receptor. Membrane-spanning TLR-2 interacts with peptidoglycan from gram-positive pathogens. This interaction stimulates signal transduction (see Figure 26.9), activating transcription factors in the nucleus. The result is transcription of genes encoding proteins that induce inflammation and other phagocyte activities. All Toll-like receptors have analogous mechanisms for activating innate immunity.

peptidoglycan components of gram-negative and gram-positive bacterial cell walls, respectively, stimulating production of antimicrobial peptides and inflammatory cytokines (Table 26.3). NOD-like receptor pyrin 3 (NLRP3) interacts with other proteins to form a structure called an **inflammasome**. Activation of the cytoplasmic inflammasome is mediated by cellular stress indicators, such as the loss of potassium ions (K^+) from damaged cells and, especially, the binding of oxidized mitochondrial DNA produced in response to LPS and released into the cytosol; the latter triggers the production of proinflammatory cytokines, initiating inflammation. Later in this chapter we discuss the soluble PRRs in the context of their ability to activate proteins that enhance phagocytosis and destruction of pathogens (Section 26.9).

Signal Transduction in Phagocytes

Interaction of a PAMP with a PRR triggers transmembrane *signal transduction*, initiating gene transcription and translation of host-response proteins in a fashion similar to the two-component regulatory systems previously discussed in *Bacteria* and *Archaea* (◀ Section 7.5). Signal transduction initiated by PAMP–PRR interaction results in enhanced phagocytosis, killing of pathogens, inflammation, and tissue healing.

For example, the binding of LPS (a PAMP derived from the cell wall of degraded gram-negative bacteria) to TLR-4 (a PRR on the surface of phagocytes) typically activates a signal transduction pathway (Figure 26.9). TLR-4 then binds proteins in the cytosol of the phagocyte, starting a cascade of reactions that activates transcription factors such as NF κ B (nuclear factor kappa B), a protein that binds to specific regulatory sites on DNA, initiating transcription of downstream genes. Many of the NF κ B-regulated genes encode host-response

proteins, such as the cytokines that activate cells and initiate inflammation (Section 26.5).

TLR-4 is an integral protein having external, transmembrane, and cytoplasmic domains. The external domain of TLR-4 binds LPS complexed with a cell surface protein called CD14 (Figure 26.9). Binding of the CD14–LPS complex by the TLR-4 external domain causes a conformational change in TLR-4 that allows the cytoplasmic domain to interact with an adaptor protein called MyD88, which then binds a protein tyrosine kinase (PTK) called IRAK4. PTKs transfer energy-rich phosphates from ATP to target-protein tyrosines that are exposed when binding alters conformation. Binding of MyD88 by IRAK4 initiates a *kinase cascade* that triggers suc-

cessive ATP-mediated phosphorylation of TRAF6, I κ K (inhibitor of kappa kinase), and I κ B (inhibitor of kappa B) proteins. Phosphorylation of I κ B causes it to dissociate from, and thereby activate, NF κ B. Activated NF κ B can then diffuse across the nuclear membrane, bind to NF κ B-binding motifs on DNA, and initiate transcription of downstream genes.

As Figure 26.9 shows, signal transduction pathways initiate activation of transcription through ligand–receptor binding on the surface of the phagocytic cell. The ligand–receptor interaction outside the cell induces the binding, recruitment, and concentration of the adaptor proteins and kinase enzymes inside the cell. A single kinase can phosphorylate many signal cascade proteins, thus amplifying the effect of a single ligand–receptor interaction. Signal transduction leading to activation of shared transcription factors and protein synthesis is also the mechanism by which lymphocytes are activated in adaptive immunity, as we discuss in Chapter 27.

Check Your Understanding

- Identify a PAMP shared by a group of microorganisms. Then, identify the cell types that use PRRs to provide innate immunity to pathogens.
- Outline the general features of a signal transduction pathway starting with binding of a PAMP by a membrane-associated PRR.

26.7 Phagocytosis and Phagocyte Inhibition

When phagocytes encounter infectious agents or their harmful products, the activation of signal transduction pathways (Figure 26.9) triggers genetic responses in the phagocyte that direct the containment

Figure 26.9 Signal transduction in innate immunity. Signal transduction is the transmission of a molecular signal across a cytoplasmic membrane by way of chemical modifications—typically involving a series of proteins in a signaling cascade—that results in a response, such as differential gene expression. In innate immunity, signal transduction is initiated when LPS, a PAMP, is bound by LBP (lipopolysaccharide-binding protein), which then transfers LPS to CD14 on the surface of a phagocyte. The LPS-CD14 complex then binds to the transmembrane TLR-4 receptor. The binding of TLR-4 initiates a series of reactions involving adaptor proteins and kinases, resulting in activation of the transcription factor NFκB. NFκB then diffuses across the nuclear membrane, binds to DNA, and initiates transcription of genes encoding proteins essential for innate immunity.

and removal of the threat—**phagocytosis** (Figure 26.10). While these mechanisms effectively protect the body from most infectious exposures, they are not foolproof; many pathogens deploy effective defenses against phagocytes in an attempt to thwart the innate immune response.

Phagocytosis and the Phagolysosome

Most phagocytes contain multiple membrane-bound inclusions called *lysosomes*, cytoplasmic vesicles containing bactericidal substances, such as toxic oxygen compounds, lysozyme, proteases, phosphatases, nucleases, and lipases. Through the molecular mechanisms we have just discussed, phagocytes identify and engage pathogens on surfaces, such as blood vessel walls or fibrin clots, before initiating phagocytosis (Figure 26.10). Activation of the phagocyte through signal transduction causes the phagocyte membrane to envelop and engulf pathogens, eventually pinching off inwardly to form a **phagosome**, a vacuole containing the engulfed pathogen. The phagosome then moves into the cytoplasm and fuses with a lysosome to form a *phagolysosome* (Figure 26.11). The toxic chemicals and enzymes within the phagolysosome kill and digest the engulfed microbial cell.

Genes that control the production of reactive oxygen compounds toxic to pathogens are highly transcribed in activated phagocytes. These reactive oxygen species include hydrogen peroxide (H_2O_2), superoxide anions (O_2^-), hydroxyl radicals ($\text{OH}\cdot$), singlet oxygen ($^1\text{O}_2$), hypochlorous acid (HOCl), and nitric oxide (NO) (Figure 26.11; ◀ Section 4.16). Phagocytic cells use these toxic oxygen compounds to kill ingested bacterial cells by oxidizing key cellular constituents. The lethal oxidative reactions are contained within the phagolysosome, and this prevents damage to the phagocyte itself.

Inhibiting Phagocytes

Some pathogens have mechanisms for neutralizing toxic phagocyte products, for killing the phagocytes, or for avoiding phagocytosis. For example, several species of *Mycobacterium* produce pigmented compounds called carotenoids that neutralize singlet oxygen and prevent pathogen killing. In addition, *Mycobacterium tuberculosis*, the bacterium that causes tuberculosis, grows and persists within phagocytic cells (▶ Section 31.4). Cells of *M. tuberculosis* use their cell wall glycolipids (◀ Section 16.11) to absorb hydroxyl radicals and superoxide anions, the most lethal toxic oxygen species produced by phagocytes (Figure 26.11).

Some intracellular pathogens produce phagocyte-killing proteins called *leukocidins*. In such cases, the pathogen is ingested as usual, but the leukocidin kills the phagocyte, releasing the pathogen unharmed. Dead phagocytes make up much of the material of *pus*, and *pyogenic* (pus-forming) pathogens such as *Streptococcus pyogenes* (scarlet and rheumatic fevers) and *Staphylococcus aureus* (skin infections) are major leukocidin producers. Localized infections by pyogenic bacteria thus form boils or abscesses.

Another important pathogen defense against phagocytosis is the bacterial capsule (◀ Section 2.6). Because the capsule prevents necessary molecular interactions between the surface of the phagocyte and that of the bacterial cell, encapsulated bacteria are often highly

J.G. Hirsch

Figure 26.10 Phagocytosis. Time-lapse phase-contrast micrographs of the phagocytosis and digestion of a chain of *Bacillus megaterium* cells by a human phagocyte. The bacterial chain is about 20 μm long.

resistant to phagocytosis. For example, fewer than ten cells of an encapsulated strain of *Streptococcus pneumoniae* can kill a mouse within a few days (◀ Section 25.3 and Figure 25.9), whereas strains lacking a capsule are harmless (◀ Figure 1.38). Surface components other than capsules can also inhibit phagocytosis. For instance, pathogenic *S. pyogenes* produces M protein, a substance that alters the surface of the pathogen and inhibits phagocytosis.

Soluble PRRs and other host molecules such as antibodies (Chapter 27) can interact with capsules and other pathogen surface molecules, thereby reversing the protective effect of bacterial defense mechanisms and enhancing phagocytosis. As an example, the vaccine

directed against *Streptococcus pneumoniae*, the agent of bacterial pneumonia, uses capsule polysaccharides to induce protective antibodies (▶ Section 28.3). Thus, the battle between pathogen and the host innate immune system is a dynamic one, where both sides deploy multiple weapons in attempts to thwart the success of the other.

Check Your Understanding

- Identify the mechanism used by phagocytes to induce pathogen killing.
- Describe several reasons why phagocytes are not always effective at removing pathogens from the body.

Figure 26.11 Activity of phagocyte enzymes in generating toxic oxygen compounds. These compounds include hydrogen peroxide (H_2O_2), the hydroxyl radical ($\text{OH}\cdot$), hypochlorous acid (HOCl), the superoxide anion (O_2^-), singlet oxygen ($^1\text{O}_2$), and nitric oxide (NO). Formation of these toxic compounds requires a substantial increase in the uptake and utilization of molecular oxygen, O_2 . This increase in oxygen uptake and consumption by activated phagocytes is called the *respiratory burst*.

IV • Other Innate Host Defenses

In addition to phagocytes, weapons and defenses of the innate immune system include generalized responses, such as inflammation and fever, antibacterial proteins of the complement system, and antiviral natural killer cells and interferons.

In addition to the physical and chemical barriers to pathogen invasion and the direct destruction of pathogens by activated phagocytes, mammalian immune systems have other inborn mechanisms that help counter infection by pathogens. Although unpleasant for the host, inflammation and fever can be effective host defense strategies for controlling microbial growth in the body and eliminating pathogens. These mechanisms, along with a consideration of the complement system and the activities of cytotoxic *natural killer cells*, round out our discussion of the innate immune response.

26.8 Inflammation and Fever

Inflammation is a complex biological response to noxious stimuli, such as physical injury, toxins, and pathogens. Inflammation is characterized by redness (erythema), swelling (edema), pain, and heat, usually localized at the site of infection or injury (Figure 26.12a). The mediators of inflammation are a group of cell activator and chemoattractant molecules, including cytokines and chemokines. Various cells, including those damaged by injury, produce these

(a)

(b)

Figure 26.12 Inflammation. (a) Photograph of a child's foot showing swelling due to infection with vaccinia virus; fluid accumulation results from the inflammatory response. (b) Photomicrograph showing infection by *Actinomyces*, a filamentous bacterium. The stained cells surrounding the dark mass of bacteria in the center are neutrophils (Figure 26.5), indicating acute inflammation.

activators. The most important chemokines and cytokines are called *proinflammatory* because of their inflammation-inducing capacity, and they are produced in high concentrations by phagocytes and lymphocytes during pathogen challenge.

Both innate and adaptive immune responses to infection can cause inflammation, and both responses trigger the release of molecules that recruit and activate effector cells, such as neutrophils. Although it is a generalized immune response, inflammation plays a crucial role to isolate and limit tissue damage by initiating the destruction of pathogen invaders and removing damaged cells as tissues are repaired. As we will soon discuss, however, the inflammatory response may also inadvertently result in considerable damage to healthy host tissue.

Inflammatory Cells and Local Inflammation

Immune-mediated inflammation is an acute response that begins at the site of pathogen entry into the body. The PRRs on macrophages and other tissue cells at the site of infection engage the

pathogen PAMPs (Figure 26.7). This activates local cells to produce and release mediators including cytokines and chemokines that interact with receptors on other cells, such as neutrophils (Figure 26.5). For example, local tissue macrophages that are activated by PAMP–PRR interaction secrete a chemokine called CXCL8. This molecule activates neutrophils to migrate along the chemokine gradient toward the source of the CXCL8, where they begin to ingest and kill the pathogen. The neutrophils, in turn, secrete even more CXCL8, attracting more neutrophils and amplifying the response, eventually destroying the pathogens (Figure 26.12b).

The chemokine and cytokine mediators released by injured cells and phagocytes contribute to inflammation. For example, macrophages and other cells at the site of infection produce proinflammatory cytokines including interleukin-1 (IL-1), IL-6, and tumor necrosis factor α (TNF- α). These cytokines increase vascular permeability, causing the edema, erythema, and local heating associated with inflammation (Figure 26.13a). Although edema stimulates local neurons, causing pain, the pressure associated with swelling also serves to force fluids away from blood vessels and into the lymphatic system, simultaneously helping to strengthen the immune response and prevent the spread of pathogens to the bloodstream. If pathogens do enter the bloodstream, a condition called *bacteremia*, this could trigger the much more serious and potentially life-threatening *septicemia* (◀ Section 25.2).

The usual outcome of the inflammatory response is a rapid localization and destruction of the pathogen by macrophages and recruited neutrophils. As the pathogens are destroyed, inflammatory cells are no longer stimulated, and as a result, their numbers at the infection site are diminished. As cytokine production decreases, the attraction of phagocytes to affected tissues lessens, and inflammation subsides.

Fever

Certain cytokines released during an inflammatory response induce **fever**, a condition of elevated body temperature. For example, the proinflammatory cytokines IL-1, IL-6, and TNF- α are *endogenous pyrogens*. These substances stimulate the hypothalamus, the temperature-controlling center of the brain, to produce *prostaglandins*, chemical signals that raise body temperature and cause fever. These same cytokines released in small amounts at local sites of infection induce localized heating, which increases blood flow and promotes healing. The release of endogenous pyrogens is a physiological response to the presence of *exogenous pyrogens*, components of pathogens that induce fever, such as the lipid A endotoxin of gram-negative bacteria LPS (◀ Section 2.4).

Although uncomfortable for the host, fever is an important component of the innate immune response to some infections. The rise from normal human body temperature, about 37°C (98.6°F), to fever temperature, usually 38–40°C (100.4–104°F), is a beneficial response to infection because higher body temperatures inhibit growth of most pathogens. Slower growth limits multiplication of the invading pathogen, thereby minimizing tissue damage and easing the workload on immune cells, especially phagocytes. Elevated body temperatures also increase the production of *transferrins*, molecules that bind and sequester iron in blood and lymph, thus depriving pathogens of this important nutrient (◀ Sections 3.1 and 25.4).

While low to moderate fever is an important component of the innate immune response, a continuous or uncontrolled rise in body temperature (>40°C) is a rare but life-threatening condition that

(a) Local infection leads to inflammation in a small part of the body, followed by healing.

(b) Systemic infection leads to inflammation and disease throughout the body.

Figure 26.13 Local and systemic inflammation. (a) Local infection, mediated by proinflammatory cytokines from local macrophages, results in inflammation that subsides as the infection is cleared. (b) Systemic infection causes systemic release of proinflammatory cytokines, resulting in widespread systemic inflammatory symptoms including severe edema, fever, and septic shock, even if the infection is controlled.

may accompany certain disease conditions and requires immediate medical intervention. This usually includes the administration of antipyretic (fever-reducing) medications, such as acetaminophen or ibuprofen, which counteract the effect of endogenous pyrogens on the hypothalamus.

Systemic Inflammation and Septic Shock

In some cases, the inflammatory response fails to localize the pathogens, and the reaction spreads throughout the body. Uncontrolled *systemic inflammation* can be more dangerous than the original infection, with inflammatory cells and mediators contributing to body-wide inflammation. An inflammatory response that spreads inflammatory cells and mediators through the entire circulatory and lymphatic systems can lead to *septic shock*, a life-threatening condition.

Although there are potentially many causes of pathogen-induced septic shock, one example is systemic infection by enteric bacteria, such as *Salmonella* species or *Escherichia coli*, which can be introduced into the peritoneal cavity or the bloodstream by a ruptured or leaking bowel. The primary infection is often cleared by the activity of phagocytes and antibiotic treatment. However, the endotoxic outer membrane LPS from these gram-negative bacteria interacts with a PRR on phagocytes, stimulating production of proinflammatory cytokines that are released into the circulation. These cytokines induce systemic responses that parallel the localized inflammatory response but on a much larger scale that affects many organ systems, ultimately

leading to a body-wide inflammatory event (Figure 26.13b). The result is a massive efflux of fluids from the central vascular tissue, causing a loss of systemic blood pressure and the influx of fluids from vascular tissues into extravascular spaces. Septic shock causes death in up to 30% of affected individuals.

Check Your Understanding

- Identify the molecular mediators of inflammation and fever and define their individual roles.
- Identify the major symptoms of localized inflammation and of septic shock.

26.9 The Complement System

The **complement system**, or simply *complement*, is a group of sequentially interacting plasma proteins, many with enzymatic activity, that functions to boost the efficiency of both innate and adaptive immune responses for the destruction of pathogens. Found throughout the body, complement proteins are produced in the liver and can be activated by the presence of a pathogen. Upon pathogen recognition, complement proteins interact with one another to trigger a cascade of events in a process called *complement activation*, the major outcomes of which are enhanced phagocytosis, inflammation, and lysis of invading cells.

The individual proteins of complement are designated as C (for complement) followed by a number or letter for the subunits, as C1, C2, C3, and so on. Complement proteins exist in an inactive conformation until they are enzymatically split to assume their active forms. The cleaving of C3 to its products, C3a and C3b, is the key event in complement activation. Three different mechanisms (pathways) are known that lead to complement activation, and we consider each of these now.

Classical Complement Activation

The *classical pathway* of complement activation is initiated when complement proteins interact with antibodies bound to pathogen surfaces. The antibodies are said to *fix* (bind) the ever-present complement proteins, and thus, classical complement activation depends upon the adaptive immune response. The complement proteins react in a defined sequence, or *cascade*, with activation of one complement protein leading to activation of the next, and so on.

The key steps of classical activation of complement, shown in **Figure 26.14a**, start with binding of antibody to antigen (initiation), followed by binding of the C1 complex (C1q, C1r, and C1s) to the antibody–antigen complex. This complex recruits and cleaves C2 into its fragments, C2a and C2b, and C4 into its fragments, C4a and C4b. C2a and C4b interact and are deposited on the pathogen surface. The resulting C2a–C4b complex functions as a *C3 convertase*, an enzyme that cleaves C3 to yield C3a and C3b. C3b then binds to the convertase, forming a *C5 convertase* that cleaves C5 into C5a and C5b. The liberated C5b then binds C6 and C7, forming a complex that inserts into the membrane of the pathogen. The C5b–7 complex recruits C8 and several copies of C9, forming a large C5b–9 unit called the *membrane attack complex* (MAC). The MAC forms a pore through the cytoplasmic membrane of the pathogenic cell, allowing extracellular fluids to rush in and lyse the cell (Figure 26.14a; see

Figure 26.14 Complement proteins and complement activation in the immune response. (a) The sequence, orientation, and activity of the components of the classical complement pathway as they interact to lyse a cell. ① Binding of the antibody and the C1 protein complex (C1q, C1r, and C1s). ② The C2a-C4b complex is a C3 convertase that splits C3. ③ The C2a-C4b-C3b complex cleaves C5, and C5b then binds an adjacent

membrane site. ④ Sequential binding of C6, C7, C8, and C9 to C5b produces a pore, the membrane attack complex (MAC), in the membrane. (b) The mannose-binding lectin (MBL) pathway. ① MBL binds to mannose on the bacterial surface and recruits C2 and C4. ② MBL anchors formation of C2a-C4b-C3b. This complex activates C5, as in step 3 of part a, and initiates formation of the MAC (step 4 in a). (c) The alternative pathway.

① C3b bound to the cell binds protein B, which is cleaved by protein D. ② The resulting C3b-Bb complex is stabilized on the membrane by factor P (properdin) and then acts on C3 in the blood, causing more C3b to bind to the membrane. Bound C3b-Bb-P then activates C5, as in step 3 of the classical activation pathway above, and initiates formation of the MAC (step 4 in a).

also Figure 26.15b). Dozens to hundreds of MACs may perforate a single bacterial cell at the point of lysis.

When activated by specific antibody, MAC formation lyses many gram-negative bacteria. However, gram-positive bacteria, such as *Streptococcus* species, are not usually lysed by complement because their thick cell walls make the cytoplasmic membrane less accessible to MAC proteins. Gram-positive bacteria can, however, be destroyed through *opsonization*.

Opsonization is the coating of pathogens with host immune proteins, such as antibodies or C3b, resulting in enhanced phagocytosis of target cells (Figure 26.15a). Opsonization neutralizes pathogens and makes them much more likely to be identified, engulfed, and destroyed by phagocytes. This is because most phagocytes, including neutrophils and macrophages, have antibody receptors (FcR) and C3b receptors (C3R) on their surfaces, which bind antibody and C3b complement protein, respectively. Normal phagocytic processes are enhanced about 10-fold by antibody-FcR interactions and amplified another 10-fold by C3b-C3R interactions.

By-products of complement activation include chemoattractants called *anaphylatoxins*; these molecules cause inflammatory reactions

at the site of complement deposition. For example, when C3 is cleaved to C3a and C3b, C3b opsonizes the target cell as described above; meanwhile, release of soluble C3a attracts and activates phagocytes, increasing phagocytosis. In addition, both C3a and the C5a cleavage product are able to bind receptors on the surface of mast cells, causing them to degranulate and release large amounts of proinflammatory histamine (Figure 26.15c).

Mannose-Binding Lectin and Alternative Pathways

The *mannose-binding lectin pathway* and *alternative pathway* of complement activation (Figure 26.14b and c) depend on recognition of shared pathogen components by complement proteins and are an important part of the innate immune response. The mannose-binding lectin (MBL) pathway depends on the activity of a serum MBL protein. MBL is a soluble PRR (Section 26.6) that binds to mannose-containing polysaccharides found only on bacterial cell surfaces (Figure 26.14b). The MBL-polysaccharide complex is similar to the C1 complex of the classical pathway (Figure 26.14a) in that it fixes C2a and C4b, again producing C3 convertase and binding

Figure 26.15 Complement proteins and the outcomes of complement activation. Each complement activation pathway leads to the production of a C3 convertase that cleaves C3 to its active products, C3a and C3b. These initiate three possible outcomes: opsonization, lysis by membrane attack complex (MAC) formation, and inflammation. (a) Pathogens coated with C3b (green) or with specific antibodies become opsonized, allowing for enhanced recognition by phagocytes through C3R and FcR proteins. (b) Transmembrane pores (white arrows) formed by MAC components C5b through C9 cause lysis of target cells. The transmission electron micrograph is a negative stain image showing human MACs attacking a foreign (rabbit) erythrocyte. (c) During complement-activated inflammation, liberated C3a and C5a bind receptor proteins on mast cells, causing the mast cells to degranulate and release proinflammatory histamine.

C3b to C2a-C4b. As before, this complex catalyzes formation of the C5–9 MAC and leads to lysis or opsonization of the bacterial cell.

The *alternative pathway* is a nonspecific complement activation mechanism that uses many of the classical complement pathway components, as well as several unique serum proteins. Together they induce pathogen opsonization and phagocytosis and activate the C5–9 MAC. C3b is produced by spontaneous hydrolysis of C3 into C3a and C3b, which occurs at low levels in the blood and tissues at

all times. If pathogens such as bacteria are present, C3b binds to the bacterial cell surface (opsonization). C3b can then bind the alternative pathway serum protein factor B, which is cleaved by factor D to yield soluble Ba and Bb (Figure 26.14c). The C3b-Bb complex may then be bound by factor P (properdin) to form C3b-Bb-P, another C3 convertase. C3b-Bb-P then attracts and cleaves additional C3, depositing more C3b on the membrane and amplifying the remaining steps of the complement cascade (Figure 26.15).

Both the alternative pathway and the MBL pathway nonspecifically target bacterial invaders and lead to activation of opsonization (Figure 26.15a) and MACs (Figure 26.15b) via formation of stable C3 convertases. MBL, factors B, D, and P, and classical complement proteins are part of the innate immune response, but unlike the classical pathway, neither the alternative pathway nor the MBL pathway requires prior antigen exposure or the presence of antibodies for activation.

We now move on to consider the immune system's response to viruses rather than bacterial pathogens. Many pathogens are viruses, and because of their small size and unique properties, special immune defense mechanisms are required to deal with them.

Check Your Understanding

- In what ways does the classical pathway of complement activation differ from the mannose-binding lectin and alternative pathways?
- What is opsonization, and how does opsonization help fight bacterial infection?
- Why are the mannose-binding lectin and alternative pathways considered part of the innate immune system?

26.10 Innate Defenses Against Viruses

In addition to opsonization and the activity of phagocytes, the immune system has other innate defenses that are especially important for controlling and eliminating viral infections. These include *natural killer cells* (Figure 26.5) and *interferons*. Natural killer cells are lymphocyte-like cells that recognize and kill compromised (unhealthy) cells, such as those infected with intracellular pathogens, in particular viruses. Whereas natural killer cells help rid the body of already infected cells, interferons, small proteins of the cytokine family, help healthy cells ward off viral infection. We consider both of these innate defenses here.

Natural Killer Cells

Natural killer cells (NK cells) are cytotoxic innate-immunity lymphoid cells that lack BCRs and TCRs and, thus, are distinct from T cells and B cells (Figure 26.5). The role of NK cells is to seek out and destroy compromised cells, such as cells infected with intracellular pathogens (such as viruses) or cancer cells (Figure 26.16). When an NK cell engages an infected or otherwise diseased cell, granules in the cytoplasm of the NK cell migrate to the contact site and release their contents against the target cell. These granules contain *perforin* and proteases called *granzymes*. Perforin binds the membrane of the target cell and forms a pore through which granzymes enter the target cell (Figure 26.16b). Granzymes are cytotoxins that cause *apoptosis*, or programmed cell death, characterized by non-inflammatory DNA degradation and membrane blebbing. During the killing process, NK cells remain unaffected and their membranes are not damaged by perforin. Also during this process, NK cell numbers do not increase nor do NK cells exhibit immune memory after interaction with target cells. With this in mind, how do NK cells recognize compromised host cells that should be destroyed? The key to this mechanism is the heterodimeric membrane protein found on the surface of most cells: the major histocompatibility complex (MHC) protein.

There are two classes of MHC proteins—*class I* and *class II*—and their primary function is to present antigen to various immune cells to trigger an immune response (Chapter 27). MHC II proteins are expressed on antigen-presenting cells (APCs) only, which include B cells, macrophages, and dendritic cells (Figure 26.5). By contrast, MHC I proteins are found on the surfaces of all nucleated cells. In uninfected cells, which contain no pathogens or foreign antigens, MHC I proteins bind and present *self peptides*, protein fragments derived from the normal degradation of self proteins, to the external environment (the term “self” here means “native to the cell”). In cells that have been infected by viruses or other intracellular

Mastering
Microbiology
Art Activity:
Figure 26.15
Natural killer
cells

Figure 26.16 Natural killer cells. Natural killer (NK) cells have two receptors: One interacts with MHC I on healthy cells; the second receptor interacts with cell stress proteins, found only on tumor cells or pathogen-infected cells. (a) Recognition of MHC I on healthy cells prevents the NK cell from releasing its toxic contents. (b) Pathogen-infected cells or tumor cells express stress proteins and often reduce MHC I expression. Especially in the absence of MHC I recognition, the NK cell interacts with the stress protein and releases perforin and granzymes, inducing apoptosis and killing the diseased cell.

pathogens, MHC I proteins display peptides derived from the infectious agent. This serves as a signal to a special type of T lymphocyte called a *T-cytotoxic cell* to destroy the infected cell.

Because MHC I proteins facilitate the destruction of cells infected with an intracellular pathogen, such as a virus, many viral genomes encode proteins that suppress expression of MHC I in host cells. Without MHC I proteins on their surfaces—a condition that is also common in cancer cells—T-cytotoxic cells cannot identify and eliminate diseased host cells. This, then, is where NK cells play a major role; NK cells recognize and destroy compromised host cells that have reduced expression of MHC I on their surfaces.

NK cells recognize and destroy pathogen-infected or tumor cells by using a two-receptor system. The molecular targets of NK cells are MHC I proteins on the surface of other cells (Figure 26.16a). As NK cells circulate and interact with other cells in the body, they use special receptors on their surfaces to recognize MHC I proteins on normal, healthy cells. Binding of the MHC I recognition receptors on NK cells to MHC I on other cells deactivates the NK cell, turning off the perforin and granzyme killing mechanisms. In addition to a deficiency of MHC I proteins, pathogen-infected or tumor cells frequently express *stress proteins* on their surfaces; NK cells have complementary receptors for many of these stress proteins. Especially in the absence of the MHC I interactions, the stress receptors on NK cells engage stress proteins on target cells. This interaction triggers the release of perforin and granzymes from the NK cell (Figure 26.16b). In this way, pathogen-infected or tumor cells that exhibit stress proteins and no longer express the MHC I proteins of healthy cells are removed from the body.

In addition to these functions, NK cells are the primary effector cells of **antibody-dependent cell-mediated cytotoxicity (ADCC)**, a process by which cells coated (opsonized) with a class of antibody called *immunoglobulin G* (IgG; ► Section 27.3) are lysed by cytotoxic immune

cells. Using special receptors on their surfaces, NK cells engage IgG antibodies that have previously bound a target cell. This interaction activates the NK cell, causing it to release its cytotoxic contents and kill the opsonized target cell.

Interferons

Interferons, in particular IFN- α and IFN- β , are small proteins in the cytokine family that prevent viral replication by stimulating the production of antiviral proteins in uninfected cells (Figure 26.17). Host cells produce and secrete interferons in response to certain viral infections or exposure to inactivated viruses or viral nucleic acids. Interferons are produced in large amounts by cells infected with viruses of low virulence, but highly virulent viruses inhibit host protein synthesis before interferon can be produced, significantly reducing interferon production. The presence of double-stranded RNA (dsRNA) also induces interferon synthesis. In nature, dsRNA exists only in certain RNA viruses, such as rhinoviruses (one of many common cold viruses, ► Section 31.7); the viral dsRNA stimulates the animal cell to synthesize and release interferon.

Antiviral interferon activities are *host-specific* rather than *virus-specific*. That is, interferon produced by a species activates receptors only on cells from the same species. As a result, interferon produced by cells of an animal in response to, for example, a rhinovirus, could also inhibit multiplication of, for example, influenza viruses in cells of the same species. However, the interferon would have no effect on the multiplication of viruses, including the original rhinovirus, in other species. We examine the potential use of antiviral interferons as chemotherapeutic or prophylactic treatments in Chapter 28.

A third type of interferon, IFN- γ , stimulates phagocytes and is produced by NK cells in response to cytokine signaling. For example, macrophages that have ingested microorganisms produce the cytokine interleukin-12 (IL-12). NK cells receive the IL-12 signal and become activated, causing them to secrete IFN- γ . The resulting exposure to IFN- γ activates the macrophages and causes them to more efficiently kill ingested microbes. As we will see in the next chapter, similar cooperation occurs between antigen-presenting phagocytes and a subset of T lymphocyte called a *T-helper cell* (► Section 27.8), and this interaction serves as a key link between innate and adaptive immunity.

Figure 26.17 Antiviral activity of interferons. Host cells secrete interferons, a type of cytokine, in response to viral infection. The interferons bind to uninfected cells, triggering a signal transduction pathway that leads to the synthesis of proteins that bind viral nucleic acids and interfere with viral replication.

Check Your Understanding

- Identify and compare the targets and the recognition mechanisms used by T-cytotoxic cells and NK cells.
- Under what conditions are interferons produced, and how do they limit the transmission of viruses from one host cell to another?

CHAPTER REVIEW

Go to **Mastering Microbiology**
for videos, animations, practice tests, and more.

I • Fundamentals of Host Defense

- 26.1** Innate immunity is an inborn protective response to infection characterized in part by recognition and elimination of common pathogens, primarily through the activity of phagocytes. Adaptive immunity is the acquired ability of the immune system to eliminate specific pathogens from the body via lymphocyte-mediated responses, including the production of antibodies that bind foreign antigens on pathogens or their products.

Q List two different types of phagocytes. How do T cells and B cells differ in their functions? From where in the human body do all of these cells originate, and which of these require maturation before they are functional?

- 26.2** The human body possesses numerous protective defenses against infectious agents. Natural host resistance to infection includes physical barriers posed by the skin and mucosa, as well as chemical barriers including acidic secretions, defensins, and lysozyme. The specificity of pathogens for particular tissues limits which hosts and tissues might be susceptible to infection.

Q How does the human normal microbiota play a role in preventing disease?

II • Cells and Organs of the Immune System

- 26.3** Cells involved in innate and adaptive immunity originate from hematopoietic stem cells in bone marrow. The blood and lymph systems circulate cells and proteins that are important components of the immune response. Diverse leukocytes participate in immune responses in all parts of the body.

Q Describe the significance of bone marrow, blood, and lymph to cells and proteins associated with the immune system.

- 26.4** Leukocytes are differentiated white blood cells derived from either myeloid or lymphoid precursor cells. Cells of myeloid lineage include monocytes and granulocytes. Monocytes include macrophages and dendritic cells, specialized phagocytes that function as antigen-presenting cells (APCs) to initiate an adaptive immune response. Granulocytes include neutrophils and eosinophils, which are phagocytes but not APCs, and basophils and mast cells, which are important inducers of the inflammatory response but may also cause allergic reactions. Lymphocytes include B and T cells, which facilitate adaptive immunity. Natural killer (NK) cells, which play a key role in destroying virus-infected and cancerous host cells, are also derived from a lymphoid precursor.

Q What is the origin of the phagocytes and lymphocytes active in the immune response?

III • Phagocyte Response Mechanisms

- 26.5** Pathogens may colonize host tissues when appropriate nutrients and growth conditions are present, such as on mucosal surfaces, especially where the composition of the normal microbiota has been altered. Innate responses to microbial invasion and tissue damage are initiated by the release of chemokines, which recruit phagocytes and other immune cells to sites of infection.

Q Describe a scenario in which microorganisms invade body tissues. What factors allow for the migration of phagocytes to sites of infection?

- 26.6** Common pathogens carry pathogen-associated molecular patterns (PAMPs) on their surfaces and intracellularly. Phagocytes recognize PAMPs through preformed (innate) pattern recognition receptors (PRRs). The recognition and interaction process stimulates phagocytes to destroy the pathogens through a signal transduction mechanism that induces phagocytosis of the infectious agent.

Q Identify some PAMPs that are recognized by PRRs. Which cells express PRRs? How do PRRs associate with PAMPs to promote innate immunity?

- 26.7** Phagocytosis is the engulfing of infectious particles by phagocytes. Engulfed pathogens are bathed in toxic oxygen compounds and enzymes inside the phagolysosome, killing and degrading them. However, some pathogens have developed various defense mechanisms to avoid or inhibit phagocytes, including secretion of leukocidins, the presence of a capsule, and biosynthesis of carotenoid pigments, which combat oxidative stress.

Q Explain how phagocytes kill microorganisms, with particular attention to oxygen-dependent mechanisms. Then identify at least three properties of pathogens that inhibit the effectiveness of phagocytes.

IV • Other Innate Host Defenses

- 26.8** Fever and inflammation, characterized by pain, swelling (edema), redness (erythema), and heat, are normal and generally beneficial outcomes that result from activation of nonspecific immune response effectors. However, uncontrolled systemic inflammation—called septic shock—or excessively high fever can lead to serious illness or death.

Q Identify the cells that initiate inflammation and the cells that are activated by inflammatory signals.

26.9 The complement system is composed of soluble proteins that catalyze bacterial opsonization and cell lysis. Complement is triggered by antibody interactions or by interactions with nonspecific activators, such as mannose-binding lectin. Complement activation may occur through either innate or antibody-dependent mechanisms. Complement may enhance phagocytosis, cause target cell lysis, or induce an inflammatory response.

Q Describe the complement system. Is the order of protein interactions important? Why or why not? Identify the components of the mannose-binding lectin pathway for complement activation. Identify the components of the alternative pathway for complement activation. How do these complement activation pathways differ from the classical pathway?

26.10 Through an antigen-independent mechanism, natural killer cells respond to both the presence of stress proteins and the absence of major histocompatibility complex (MHC) I on the surface of virus-infected cells or tumor cells, using perforin and granzymes to kill the compromised target cells. Interferons are cytokines produced by virus-infected cells that limit the spread of infection by stimulating the expression of antiviral proteins in uninfected cells. Other interferons activate phagocytes to enhance phagocytosis.

Q What is the activation signal for NK cells? How does this differ from the activity of T-cytotoxic lymphocytes?

APPLICATION QUESTIONS

- Describe the relative importance of innate immunity compared to adaptive immunity. Is one more important than the other? Could humans survive in a normal environment without an immune system?
- Describe the potential problems that would arise if a person had an acquired inability to phagocytose pathogens. Could the person survive in a normal environment such as a college campus? What defects in the phagocyte might cause lack of phagocytosis? Explain.
- Inflammation is the hallmark of an active immune response. Explain how inflammation is triggered by innate immune mechanisms. Why does inflammation subside as an infection is controlled?
- Do you agree with the following statement? Complement is a critical component of antibody-mediated defense. Explain your answer. What might happen to persons who lack complement component C3? C5? Factor B (alternative pathway)? Mannose-binding lectin (MBL)?

CHAPTER GLOSSARY

Adaptive immunity the acquired ability to recognize and destroy a particular pathogen or its products, dependent on previous exposure to the pathogen or its products

Antibody a soluble protein produced by B cells and plasma cells that interacts with antigen; also called immunoglobulin

Antibody-dependent cell-mediated cytotoxicity (ADCC) the process by which NK cells bind IgG-coated target cells and kill them by secreting cytolytic toxins

Antigen a molecule capable of interacting with specific components of the immune system and that often functions as an immunogen to elicit an adaptive immune response

Antigen-presenting cell (APC) a macrophage, dendritic cell, or B cell that takes up and processes antigen and presents it to T-helper cells

Basophil a circulating granulocyte that contains granules of inflammatory mediators that, in some cases, contribute to allergic reactions

B cell a lymphocyte that has immunoglobulin surface receptors, produces immunoglobulin, and may present antigens to T cells

B cell receptor (BCR) a cell surface immunoglobulin that acts as an antigen receptor on a B cell

Chemokine a soluble protein that recruits immune cells to an injury site; a type of cytokine

Complement system a series of proteins that react sequentially with antibody–antigen complexes, mannose-binding lectin, or alternative activation pathway proteins to amplify or potentiate target cell destruction

Cytokine a soluble protein produced by a leukocyte or damaged host cell; modulates an immune response

Dendritic cell a phagocytic antigen-presenting cell found in various body tissues; transports antigen to secondary lymphoid organs

Epitope the portion of an antigen that reacts with a specific antibody or T cell receptor

Eosinophil a phagocytic granulocyte especially active against extracellular parasites, such as helminths

Fever an increase in body temperature resulting from infection or the presence of toxins in the body

Granulocyte a leukocyte derived from a myeloid precursor that contains cytoplasmic granules consisting of toxins or enzymes that are released to destroy target cells

Hematopoiesis the process by which precursor stem cells in the bone marrow or gut differentiate into any type of blood cell

Hematopoietic stem cell a progenitor cell found primarily in the bone marrow but also in the gut that can differentiate into any of a variety of blood cells

Immune memory (memory) the ability to rapidly produce large quantities of specific immune cells or antibodies after subsequent exposure to a previously encountered antigen

Immunity the ability of an organism to resist infection

Immunoglobulin a soluble protein produced by B cells and plasma cells that interacts with antigen; also called antibody

Inflammasome a cytosolic signaling complex that contains NOD-like receptor pyrin 3 (NLRP3) and mediates the activation of potent proinflammatory cytokines

Inflammation a nonspecific reaction to noxious stimuli such as toxins and pathogens, characterized by redness (erythema), swelling (edema), pain, and heat, usually localized at the site of infection

Innate immunity the inherent ability to recognize and destroy an individual pathogen or its products that does not rely on previous exposure to a pathogen or its products

Interferons cytokine proteins produced by virus-infected cells that induce signal transduction in nearby cells, resulting in transcription of antiviral genes and expression of antiviral proteins

Invasion the ability of a pathogen to enter into host cells or tissues, spread, and cause disease

Leukocyte a nucleated cell in blood; also called a white blood cell

Lymph nodes organs that contain lymphocytes and phagocytes arranged to encounter microorganisms and antigens as they travel through the lymphatic circulation

Lymphocytes a subset of nucleated cells in blood involved in the adaptive immune response; B cells and T cells

Macrophage a large leukocyte found in tissues that has phagocytic and antigen-presenting capabilities

Major histocompatibility complex (MHC) a genetic region that encodes several proteins important for antigen processing and presentation; MHC I proteins are expressed on all nucleated cells, whereas MHC II proteins are expressed only on antigen-presenting cells

Mast cell tissue granulocyte similar in function to basophils that contains intracytoplasmic granules with inflammatory mediators

Monocyte Circulating phagocyte that contains many lysosomes and can differentiate into a macrophage or dendritic cell

Mucosa-associated lymphoid tissue (MALT) a part of the lymphatic system that interacts with antigens and microorganisms that enter the body through mucous membranes, including those of the gut, the genitourinary tract, and the respiratory tract

Natural killer (NK) cell a specialized lymphocyte that recognizes and destroys infected host cells or cancer cells in a nonspecific manner

Neutrophil a leukocyte exhibiting phagocytic properties, a granular cytoplasm (granulocyte), and a multilobed nucleus; also called polymorphonuclear leukocyte or PMN

Opsonization the deposition of antibody or complement protein on the surface of a pathogen or other antigen that results in enhanced phagocytosis

Pathogen-associated molecular pattern (PAMP) a repeating structural component of a microorganism or virus recognized by a pattern recognition receptor (PRR)

Pattern recognition receptor (PRR) a protein that is soluble or bound to a phagocyte membrane and that recognizes a pathogen-associated molecular pattern (PAMP)

Phagocyte a cell that engulfs foreign particles, and can ingest, kill, and digest most pathogens

Phagocytosis a mechanism for ingesting particulate material in which a portion of the cytoplasmic membrane surrounds the particle and brings it into the cell; for phagocytes of the immune system, the process of engulfing and killing foreign particles and cells

Phagosome an intracytoplasmic vacuole containing engulfed materials, especially pathogens or foreign particles

Plasma the liquid portion of the blood containing proteins and other solutes

Plasma cell a differentiated B cell that produces soluble antibodies

Primary lymphoid organ an organ in which antigen-reactive lymphocytes develop and become functional; the bone marrow is the primary lymphoid organ for B cells; the thymus is the primary lymphoid organ for T cells

Secondary lymphoid organ an organ at which antigens interact with antigen-presenting phagocytes and lymphocytes to generate an adaptive immune response; these include lymph nodes, spleen, and mucosa-associated lymphoid tissue (MALT)

Serum the liquid (noncellular) portion of the blood with clotting proteins removed

Specificity the ability of cells of the adaptive immune response to interact with particular antigens

T cell a lymphocyte that interacts with antigens through a T cell receptor for antigen; T cells are divided into functional subsets including Tc (T-cytotoxic) cells and Th (T-helper) cells. Th cells are further subdivided into Th1 (inflammatory) cells and Th2 cells, which aid B cells in antibody formation

T cell receptor (TCR) an antigen-specific receptor protein on the surface of T cells

Toll-like receptor (TLR) one of a family of pattern recognition receptors (PRRs) found on phagocytes, structurally and functionally related to Toll receptors in *Drosophila*, that recognize a pathogen-associated molecular pattern (PAMP)

MICROBIOLOGYNOW

Controlling HIV through “Public” T Cell Receptors on CD4 T Cells

Control of human immunodeficiency virus (HIV) proliferation in infected individuals typically requires surveillance of viral activity and *highly active anti-retroviral therapy* (HAART; see Section 31.15). HAART requires administration of combination anti-retroviral drugs to reduce the viral load and prevent HIV mutation into drug-resistant strains. However, in a small fraction (<1%) of cases, HIV-positive individuals exhibit natural resistance to HIV and maintain an undetectable viral load even in the absence of HAART. These rare individuals, termed “HIV controllers,” maintain high numbers of CD4 T cells that produce a robust immune response against HIV.

As discussed in this chapter, CD4 T cells (see scanning electron micrograph) are “helper” T cells that secrete cytokines to coordinate the adaptive immune response. This is initiated through the interaction of T cell receptors (TCRs), found on the surface of T cells, with antigens presented on major histocompatibility complex (MHC) proteins expressed on the surface of antigen-presenting cells. MHC proteins are encoded by human leukocyte antigen (HLA) genes, and

because of a phenomenon called *polymorphism*, many different HLA alleles occur in the human population.

Research has shown that HIV controllers produce CD4 T cells with high-affinity “public” TCRs that recognize a highly conserved HIV capsid epitope called *Gag293* when presented by a broader than usual array of distinct HLA class II molecules. By generating an especially efficient “immunological synapse”—the highly organized interaction that occurs when a TCR engages antigen presented by MHC proteins—the public TCRs conferred unusual cytotoxic activity on the CD4 T cells, allowing them to selectively destroy HIV-infected host cells. This property appears to be a key factor in suppressing HIV replication in HIV controllers and suggests that high-affinity public TCRs are linked to spontaneous control of HIV infection, a finding that ultimately may prove to be of enormous clinical significance.

In the previous chapter we discussed the key features of innate immunity and how this system protects against infection and disease from a broad range of pathogens. Here, we build on this foundation with a focus on the powerful and highly specific immune mechanisms of adaptive immunity, mechanisms that depend on both cellular and molecular components and that complement the innate response.

I • Principles of Adaptive Immunity

Adaptive immune mechanisms are highly specific and exhibit immune memory. B and T lymphocytes are the primary effector cells activated in response to immunogen exposure.

Innate and adaptive immunity can be viewed as two arms of the immune response that work together to protect the host from attack by foreign substances. Whereas innate immunity is characterized by broadly targeted responses triggered by *common* structural features found on microorganisms, adaptive immunity is directed toward *specific* molecular components of the microbes (their antigens). Thus, it is the individual antigenic properties of different pathogens that orchestrate the adaptive immune response.

We begin this part of the chapter by considering the major characteristics of the adaptive immune response and explore how adaptive immune responses are tailored to address invasions from various pathogens, including viruses, bacteria, and fungi.

27.1 Specificity, Memory, Selection Processes, and Tolerance

Adaptive immunity is primarily a function of B and T lymphocytes. B lymphocytes (B cells) specialize in the production of antibodies that interact with and protect against extracellular antigens, thus conferring *antibody-mediated (humoral) immunity* on the host. T lymphocytes (T cells) express antigen-specific receptors called **T cell receptors (TCRs)** on their surfaces that defend against intracellular pathogens, such as viruses and certain bacteria, thus conferring *cell-mediated (cellular) immunity* on the host. The combination of antibody-mediated and cell-mediated defenses comprises adaptive immunity, a system that is characterized by three major features: *specificity*, *memory*, and *tolerance*. None of these features is characteristic of the innate immune response (Chapter 26).

Immune Specificity and Memory

Overall, the immune response is highly specific, but the innate and the adaptive systems differ in their degree of specificity. Innate immunity is activated upon recognition of features common to a broad diversity of microorganisms, such as the peptidoglycan of all gram-positive bacteria or the lipopolysaccharide (LPS) of all gram-negative bacteria. By contrast, adaptive immune mechanisms are directed against pathogen-specific antigens, such as a specific protein associated with a single strain of a particular pathogen.

Each B cell or T cell expresses protein receptors that exhibit **specificity** for a single type of antigen. Just as T cells have antigen-binding TCRs on their surfaces, the antigen-binding proteins of B cells are membrane-bound immunoglobulins called **B cell receptors (BCRs)**.

The specificity of the antigen–BCR or antigen–TCR interaction is dependent on the capacity of the lymphocyte cell receptor to interact with a particular antigen but not with other antigens (**Figure 27.1a**). A pathogen that invades the body introduces multiple antigens that are specific to that pathogen, and each of these antigens will be

Specificity: Lymphocytes have surface receptors that interact with individual antigens.

(a)

Memory: The first antigen exposure induces multiplication of antigen-reactive cells, resulting in multiple copies, or *clones*. After a subsequent exposure to the same antigen, the immune response is faster and stronger due to the large number of responding cells.

(b)

Immune responses: As a result of immune memory, antigen reexposure triggers a much stronger secondary response.

(c)

Figure 27.1 Specificity and memory in the adaptive immune response. Key features of antibody-mediated and cell-mediated immunity are (a) specificity and (b) memory. (c) The primary response induces both immune cells and antibodies. The antigens given at day 0 and day 100 must be identical to induce a secondary response. The secondary response may generate more than 10-fold increases in immune cells and antibody concentrations.

recognized by distinct lymphocytes bearing receptors that specifically bind them.

In addition to specificity, the adaptive immune system exhibits **memory (immune memory)** (Figure 27.1b). Lymphocytes must encounter antigen to proliferate in the body and, in the case of B cells, stimulate production of detectable and effective antigen-activated antibodies. The first exposure to an antigen generates a **primary immune response** in which antigen recognition by specific B or T lymphocytes leads to B and T cell activation, proliferation, and differentiation, thereby resulting in large numbers of antigen-specific B and T cell **clones**. Some of these clones differentiate into long-lived **memory cells**, cells which persist in the body for years and confer long-term antigen-specific immunity. Subsequent exposure to the same antigen activates these clones and generates a faster and stronger **secondary immune response** that peaks within a few days (Figure 27.1c). This capacity to respond more quickly and vigorously to subsequent exposures to the eliciting antigen provides the host with immediate resistance to previously encountered pathogens, a topic we develop in more detail in Section 27.3. Immune memory is one of the most important outcomes of an immune response because vaccinating humans or other animals with killed or weakened pathogens (or their products) is a major and relatively inexpensive means of conferring immunity to dangerous pathogens; this in turn promotes long-term public health (see Section 27.2).

T Cell Selection and Tolerance

The adaptive immune system must be able to discriminate between harmless *host* antigens (“self”) and potentially dangerous *foreign* antigens (“nonself”) and function to destroy only the latter. T cells undergo immune selection for potential antigen-reactive cells and selection *against* those cells that react strongly with self antigens. Selection against self-reactive cells results in the development of another key characteristic of the adaptive immune response: **tolerance**. Tolerance is a key component of the immune response and ensures that adaptive immunity is directed against agents that pose genuine threats to the host and not against the host’s own proteins. The failure to develop tolerance may result in dangerous reactions to self antigens, a condition called *autoimmunity* (► Section 28.1).

T lymphocyte precursors leave the bone marrow via the bloodstream and enter the thymus (Figure 27.2); the thymus and bone marrow are the *primary lymphoid organs* (◄ Section 26.4). During the process of T cell maturation in the thymus, immature T cells undergo a two-step selection process to (1) select potential antigen-reactive cells (positive selection) and (2) eliminate cells that react strongly with self antigens (negative selection). **Positive selection** requires the interaction of immature T cells in the thymus with peptide antigens that are actually of self origin. As we discussed in Chapter 26, T cells interact only with antigens that are presented on *major histocompatibility complex proteins* (MHCs) expressed on the surface of host cells. Using their TCRs, some immature T cells bind to MHCs that present self peptides on the thymic epithelial tissue. The T cells that do not bind MHC–peptide complexes will be of no use in the immune response and are therefore permanently eliminated via *apoptosis* (programmed cell death). By contrast, those T cells that bind thymic MHC proteins receive survival signals and therefore remain viable. Positive selection retains T cells that recognize self-peptide:self-MHC and deletes T cells that do not recognize

self-peptide:self-MHC and would therefore be unable to recognize MHC–peptide outside the thymus.

The second aspect of T cell maturation is **negative selection**. In this process, the positively selected T cells continue to interact with thymic MHC–peptide. Precursor T cells that recognize self-peptide:self-MHC *too strongly* could potentially mount a harmful immune response against host tissues, and therefore these cells are eliminated by apoptosis. The removal of self-reactive precursor T cells through the processes of positive and negative selection is called **clonal deletion**, and this important mechanism prevents the propagation of precursor T cells that could potentially cause autoimmune complications. Precursor T cells having TCRs that react less strongly with self-peptide:self-MHC survive negative selection and continue further differentiation (Figure 27.2).

This two-stage T cell selection in the thymus ensures the generation of self-tolerant T cells capable of reacting strongly to foreign antigens only. Precursor T cells that are either useless (do not bind) or harmful (bind too tightly) are deleted in the thymus. Approximately 95–98% of all immature T cells do not survive the thymic selection process. The remaining selected T cells are destined to interact very strongly with nonself antigens. They are not destroyed in the thymus because their weak binding interactions with thymic self antigens signal them to proliferate. The selected and growing T cells leave the thymus and migrate to the spleen, mucosa-associated lymphoid tissue (MALT), and lymph nodes—the *secondary lymphoid organs or tissues*—where they can engage foreign antigens presented by B cells and other antigen-presenting cells (APCs).

B Cell Selection and Tolerance

To respond to the nearly infinite variety of environmental antigens, the immune system must have the capacity to generate an essentially limitless variety of antigen-specific lymphocytes. To this end, and as we shall see in Section 27.4, the body produces an enormous diversity of B cells, each expressing on its surface BCRs that are specific for a single antigen. B cell selection occurs in the *bone marrow*—the primary lymphoid organ responsible for B cell maturation in mammals—when each immature B cell is exposed to self antigen. As with T cells, the development of tolerance in B cells is necessary because antibodies produced by self-reactive B cells (autoantibodies) may cause autoimmunity and damage to host tissues (► Section 28.1). Therefore, B cells must undergo their own clonal deletion process. Immature B cells whose BCRs bind to self-cell-surface antigens undergo apoptosis and are removed from the B cell repertoire. B cells whose BCRs do not react with self antigens complete development and migrate to peripheral tissues.

In the periphery (secondary lymphoid tissues), any B cell that recognizes (binds to) its specific foreign antigen becomes activated and can then proliferate and differentiate in a process called **clonal expansion** (Figure 27.3). This produces a pool of B cells, each of which expresses identical antigen-specific receptors. B cells that have not interacted with antigen are not activated and, therefore, do not proliferate. B cell activation and clonal expansion may occur from encountering either T-independent or T-dependent antigens. *T-independent antigens* are typically common microbial components composed of repeating subunits, such as lipopolysaccharides and bacterial capsules. Cross-linking of BCRs by T-independent antigens activates the B cell and triggers clonal expansion in the absence of

Figure 27.2 T cell selection and clonal deletion. T cells undergo positive selection for functionality and negative selection for dangerously strong recognition of self antigens in the thymus.

T cell help. Although relatively rapid, immune responses to T-independent antigens are comparatively weak, producing antibody-secreting *plasma cells* but no long-lived memory cells.

B cells that interact with *T-dependent antigens*, which are typically pathogen-specific peptides, must engage a corresponding *T-helper (Th) cell* (Section 27.8) to become activated and generate a clone of antigen-specific B cells. Upon activation, the newly produced B cells differentiate primarily into antibody-producing plasma cells but also a smaller population of antigen-specific memory cells (Figure 27.3).

It is the production of memory cells that confers long-term immunity to the eliciting antigen. Upon subsequent exposure to the same antigen, memory B cells do not require T cell help for activation and, therefore, are able to rapidly undergo clonal expansion and trigger an adaptive response. We explore these concepts further in Section 27.3.

In addition to clonal deletion, **clonal anergy** (clonal unresponsiveness) also plays a role in final selection of the B cell pool. Some immature B cells are reactive to self antigens but are not activated by them. This is because in addition to antigen recognition, B cell

Figure 27.3 B cell clonal selection and expansion. Among the repertoire of individual B cells (represented by B cell₁, B cell₂, and B cell₃), only B cell₂ specifically interacts with the introduced antigen (shown as a star). The antigen drives selection and, following interaction with a Th cell, proliferation of B cell₂ to form a clone of antigen-specific B cells. Clonal copies of the original antigen-reactive B cell have the same antigen-specific surface antibody. Continued exposure to antigen results in continued expansion of the clone. Clones differentiate further into many antibody-producing plasma cells and comparatively few long-lived memory B cells. Compare this figure with Figure 27.6.

activation requires a *second signal* from a T-helper cell. The nature of this second signal is a positive interaction between proteins on the surface of B cells and Th cells that triggers the release of cytokines, especially IL-4 (interleukin-4), from the Th cell that activates the B cell. If no second signal is generated because the available Th cells have been rendered tolerant to the antigen in the thymus, the B cell remains unresponsive. Using a similar mechanism, a second signal is also required to activate T cells that are interacting with antigens presented on MHCs (Section 27.7). The requirement for a second activation signal is the key to establishing and maintaining clonal anergy in potentially dangerous self-reactive B and T lymphocytes.

With their key properties of specificity, memory, and tolerance, lymphocytes stand ready to deploy the adaptive immune response. The selection and control processes just described ensure that this response will be directed only against foreign antigens. We now examine the nature of antigens in more detail and consider the basic classes of adaptive immunity.

Check Your Understanding

- Distinguish between immune specificity, memory, and tolerance.
- Distinguish between positive and negative T cell selection. How do positive selection and negative selection contribute to the development of tolerance in T cells?
- Distinguish between clonal deletion and clonal anergy in B cells.

27.2 Immunogens and Classes of Immunity

The adaptive immune response can be induced by a vast range of foreign antigens. As we have discussed, **antigens** are substances that interact with antibodies or TCRs. Most, but not all, foreign antigens are **immunogens**, substances that induce an immune response.

Here we examine the features of effective immunogens, define the features of antigens that promote interactions with antibodies and TCRs, and discuss the classes of immunity.

Immunogens and Antigen Binding

Immunogens share several intrinsic properties that enable them to induce an adaptive immune response. First, *molecular size* is an important property of immunogenicity; for a molecule to be immunogenic, it must be sufficiently large. Certain low-molecular-weight compounds called *haptens*—such as the disaccharide lactose—do not induce immune responses themselves. However, antibodies can still bind haptens, and they may induce an immune response if attached to a larger *carrier* molecule. Because antibodies can bind them, haptens are considered antigens, but they are not themselves immunogens. Proteins and complex carbohydrates are effective immunogens, whereas nucleic acids, simple polysaccharides with repeating subunits, and lipids are typically not. Thus, *sufficient molecular complexity* is another key property of immunogenicity. Finally, unlike soluble molecules, large, insoluble macromolecules are usually excellent immunogens because phagocytes readily engulf and process them. Thus, *appropriate physical form* is another intrinsic property of immunogenicity.

Extrinsic factors, such as the immunogen dose and the route of administration, also influence immunogenicity. The administered dose of an immunogen can be important for an effective immune response, and in general, doses of 10 µg to 1 g are effective in most mammals. Immunogens administered parenterally (outside of the gastrointestinal tract), usually by injection, are normally more effective than those given topically or orally. When administered by oral or topical routes, antigens may be significantly degraded before coming in contact with immune cells and, as a result, may exhibit diminished or no immunogenicity.

Figure 27.4 Antigen and epitopes for antibodies. Antigens may contain several different epitopes, each capable of reacting with a different antibody (Ab). In some cases, epitopes may be formed from nonlinear parts of a folded polypeptide, as is the case for epitope 1, recognized here by Ab₁. The folding brings two distant portions of the polypeptide together to make a single epitope.

As discussed in Chapter 26, an antibody or TCR does not interact with an immunogen as a whole but only with a distinct portion of the molecule called an **epitope** (also called an *antigenic determinant*) (Figure 27.4). Epitopes may include sugars, short peptides of four to six amino acids, and other organic molecules that are components of a larger immunogen. Antibodies are able to recognize epitopes on proteins or polysaccharides in their native conformations. By contrast, TCRs recognize epitopes only after the antigens have been partially degraded or *processed* into peptides by antigen-presenting cells or target cells. T cells recognize peptides shorter than about 20 amino acids presented to them in association with MHC molecules on the surface of host cells.

Antibodies and TCRs can discriminate between closely related epitopes. However, specificity is not absolute, and an individual antibody or TCR may interact to some extent with several different but structurally similar epitopes. The antigen that induces the production of an antibody and, in turn, interacts with that antibody is

called the *homologous* antigen, whereas any noninducing antigens that interact with the antibody are called *heterologous* antigens. An interaction between an antibody or a TCR and a heterologous antigen is called a *cross-reaction*.

The engagement of BCRs and TCRs on lymphocytes with naturally encountered immunogens induces an adaptive immune response that often leads to long-term immunity. But as we now discuss, immunity may also be conferred either by purposely introducing an eliciting antigen (vaccination) or through passive transfer mechanisms, administered either naturally or artificially.

Classes of Adaptive Immunity: Active and Passive

There are two broad classes of adaptive immunity. *Active* adaptive immunity may develop following a natural or intentional exposure to an immunogen. By contrast, *passive* adaptive immunity is generated from the transfer of antibodies or immune cells from an immune individual to a nonimmune one. Active and passive immunity are illustrated in Figure 27.5 and contrasted in Table 27.1.

Active and passive immunity can be further classified as being either natural or artificial. *Natural active immunity* is the outcome of exposure to antigens through infection and is typically mediated by both B and T cells. By contrast, *natural passive immunity* occurs when a nonimmune person acquires immune cells or antibodies through natural transfer of cells or antibodies from an immune person, such as from a mother to her fetus before birth or from a mother to a newborn through breastfeeding (Figure 27.5).

Artificial active immunity is conferred by **vaccination (immunization)** and is a major weapon for the prevention and treatment of many infectious diseases. The introduction of antigen into the host triggers B and T cell activation, resulting in antibody production in a primary immune response and, more importantly, production of a population of immune memory cells. A second dose, often called a “booster,” of the same antigen results in a secondary immune response in which existing memory cells are quickly activated, producing much higher levels of antibodies and a larger

Figure 27.5 Active and passive immunity. Photos, left to right: (1) Childhood measles showing typical systemic measles rash. Natural active immunity requires infection with a pathogen to activate the adaptive immune response. (2) Vaccination by nasal inhalation of antigen. Artificial active immunity occurs from exposure to particular antigens in a vaccine. (3) A 1934 United States government poster promoting breastfeeding. Natural passive immunity occurs when immunity is transferred from one individual to another by natural means, such as the transfer of maternal antibodies in breast milk. (4) Timber rattlesnakes produce highly toxic venom. An antivenom consisting of purified antibodies to timber rattlesnake venom can be prepared in horses and artificial passive immunity conferred on a snakebite victim by injecting the victim with the antivenom.

TABLE 27.1 A comparison of active and passive immunity	
Active immunity	Passive immunity
Exposure to antigen; immunity achieved by purposely administering antigen or through infection	No exposure to antigen; immunity achieved by injecting antibodies or antigen-reactive T cells
Specific immune response made by individual achieving immunity	Specific immune response made by the donor of antibodies or T cells
Activated by antigen; immune memory in effect	No immune system activation; no immune memory
Maintained via stimulation of memory cells (i.e., booster immunization)	Cannot be maintained and decays rapidly
Develops over a period of weeks	Develops immediately

population of immune memory cells (Figure 27.1c). Active immunity may persist throughout life as a result of immune memory.

Artificial passive immunity is conferred when an individual receives antibodies from an immune individual through injection of an *antiserum*. In passively immunized individuals, transferred antibodies gradually disappear from the body, no immune memory is conferred, and a later exposure to the antigen does not elicit a secondary response. Artificial passive immunity is often used as postexposure therapy for acute infectious diseases, such as tetanus or rabies, for individuals not already protected against such diseases by previous vaccination. This approach is also used for treating individuals following bites from venomous animals (antivenom, Figure 27.5). Antisera containing a concentrated suspension of antibodies specific to the venom (toxin) are generated in large immunized animals, such as horses, or obtained from humans following a natural or artificial active immune response against the antigen and stored for use when needed to treat a human or other animal from a potentially fatal toxemia.

Check Your Understanding

- Identify the intrinsic and extrinsic properties of an immunogen.
- Describe an epitope recognized by an antibody and compare it to an epitope recognized by a TCR.
- Give an example for each: natural and artificial active immunity and natural and artificial passive immunity.

II • Antibodies

In response to the presence of immunogens, B cells produce antibodies (immunoglobulins) to specifically bind, neutralize, and—with the help of other immune cells—eliminate foreign substances from the body.

Antibodies provide antigen-specific immunity that protects against pathogens and dangerous soluble proteins, such as toxins. Here we look at the production, structural diversity, and antigen-binding function of antibodies. We also consider the organization and recombination of genes that encode antibodies, which underlie the nearly unlimited potential for the adaptive immune response to react to foreign molecules.

27.3 Antibody Production and Structural Diversity

An antibody, or *immunoglobulin* (Ig), is a soluble protein made by a B lymphocyte or a plasma cell (◀ Figure 26.5) in response to antigen exposure. Each antibody binds to a specific antigen. Antibodies help control the spread of infections by recognizing and binding antigens from pathogens and their products in extracellular environments, such as blood and mucus secretions, and in so doing facilitate the removal of these foreign substances from the body by a variety of mechanisms.

B Cells, Antibodies and Their Activities, and Memory

Each B cell has about 100,000 immunoglobulins of identical antigen specificity that function as B cell receptors (BCRs) on the cell’s surface. To make antibodies, a B cell must first bind antigen by way of its BCR (Figure 27.6). The BCR–antigen interaction causes the B cell to ingest the bound antigen by endocytosis. The B cell then digests the antigen and generates from it a suite of pathogen-derived antigenic peptides that are affixed to proteins of the *class II major histocompatibility complex* (MHC II) (Section 27.5) and displayed (*presented*) on the surface of the B cell. The B cell now functions as an antigen-presenting cell and presents the MHC II–peptide complex to a *T-helper* (*Th*) cell, which in turn stimulates the B cell to proliferate and differentiate into antibody-secreting plasma cells and memory B cells (Figure 27.6). We consider MHCs and T cells in more detail later in this chapter.

Th cells do not interact directly with pathogens but instead stimulate, or “help,” other immune cells, such as B cells and macrophages, to become activated to carry out an immune response. In this case, the cell being “helped” is the antigen-presenting B cell on which the Th cell recognized the MHC II–peptide complex. The recognition of the MHC II–peptide complex on the B cell surface by a cognate Th cell (the Th cell with a TCR specific for that peptide) stimulates the Th cell to produce cytokines and express cell surface receptors that, in turn, stimulate antigen-specific B cells to grow and divide. This results in the expansion of B cell clones having specificity to the original antigen. Activated B cell clones also differentiate into plasma cell clones, each with the ability to produce and secrete large amounts of antibodies of identical antigenic specificity (Figure 27.6). This primary antibody response (Figure 27.1c) is detectable within about five days after antigen exposure, and serum levels of antibodies reach their peak within a few weeks.

Some of the activated B cell clones remain in circulation in the immune system as long-lived *memory B cells* (Figure 27.6). Subsequent exposure to the same antigen, for example by reinfection with the same pathogen, stimulates the antigen-reactive memory B cells, producing a secondary antibody response characterized by more efficient production of higher quantities of high-affinity antibodies (Figures 27.1c and 27.6). Recall that the secondary response, conferred by immune memory, is the basis for vaccination (Section 27.2).

Antibodies released from plasma cells interact with antigen, which is often located directly on a pathogen. Antibody binding may have multiple effects on a pathogen, but most antibody interactions do not directly kill pathogens; instead they block interactions between pathogens (or their products) and host cells. For example, antibodies present on mucous membranes may specifically interact

Figure 27.6 B cell–T cell interaction and antibody-mediated immunity. B cells interact with antigen and Th cells to produce antibodies. B cells initially function as antigen-presenting cells. First, their antigen-specific Ig receptor traps antigen. Following endocytosis, antigens are processed into peptide fragments, which are bound by MHC II and transported to the B cell surface. The MHC II–peptide complex is bound by the TCR on the Th cell, causing the Th cell to secrete IL-4 and IL-5. These cytokines activate the B cell to produce clones that differentiate into many antibody-producing plasma cells and a smaller number of memory cells. The latter are long-lived and can differentiate into antibody-producing plasma cells upon secondary exposure to the same antigen.

with influenza virus antigens able to bind to host cells, thereby blocking attachment of the influenza virus to host cells on the mucosal surface. In addition, circulating antibodies in blood and lymph serum can *neutralize* toxins by binding them and thereby prevent their deleterious effects on host cells (Figure 27.7). In other cases, antibodies coat pathogens by binding to their surface antigens, a process called *opsonization*, thereby marking them for destruction by receptor-mediated phagocytosis (◀ Section 26.9). Phagocytes have antibody receptors called *Fc receptors* (FcR) that bind to any antibody attached to an antigen, resulting in enhanced phagocytosis of the antibody-coated pathogens (◀ Figure 26.15a).

Immunoglobulin G Structure and Function

There are five classes of immunoglobulins—IgG, IgM, IgA, IgD, and IgE—distinguished from one another by their different physical, chemical, and immunological properties. Based on these distinctions, each antibody class has a defined distribution and general function (Table 27.2). IgG is the most common circulating antibody, comprising up to 80% of serum immunoglobulins, and it can activate complement through the classical pathway (◀ Section 26.9). IgG is composed of four polypeptide chains that are interconnected by disulfide (S—S) bonds (Figure 27.8). In each IgG molecule, two identical short chains of about 25 kilodaltons (kDa) (called *light*

Figure 27.7 Neutralization of an exotoxin by an antitoxin antibody. (a) Toxin results in cell destruction. (b) Antitoxin prevents cell destruction. Examples of exotoxins include botulism and tetanus toxins and are discussed in Section 25.6.
